"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

THURSDAY, NOVEMBER 7, 1889.

TWENTY YEARS.

A REMINDER that to-day is the twentieth anniversary of the first issue of NATURE, will not, perhaps, be without interest to our readers, and certainly affords food for reflection to those who in various capacities have been more or less closely connected with this journal from the first.

"When another half-century has passed," said Prof. Huxley in our first number, "curious readers of the back numbers of NATURE will probably look on *our* best 'not without a smile.'"

It will probably be so, but though twenty years is hardly a sufficient interval to make our smiles at our earlier efforts supercilious, it is enough to test whether progress has been made, and whether the forward path is pursued with growing or with waning force.

As regards this journal itself, we may claim that it has not disappointed the hopes of its founders, nor failed in the task it undertook; and we make this claim all the more emphatically because we feel that what has been accomplished has not been due to our own efforts so much as to the unfailing help we have always received from the leaders in all branches of natural science. This help has not been limited to their contributions to our columns, but has consisted also of advice and suggestions which have been freely asked and as freely given. Not the least part of our duty, and even privilege, to-day is to state openly how small our own part has been, and to render grateful thanks to those to whom it is chiefly due that NATURE has a recognized place in the machinery of science, and has secured an audience in all parts of the civilized world.

We do not wish, however, to narrow our retrospect of the last twenty years by confining our attention to the measure of success which these pages have won. It has been attained, as we have shown, by the aid of nearly all the best-known scientific writers and workers, not in Britain only but in many countries old and new; and we cannot believe that they would thus have banded themselves together if evidence had not been given of an honest desire for the good of science and for the "promotion of natural knowledge," or if the attainment of these objects had not been regarded by us as of more importance than a journalistic success. Thus, on its twentieth birthday, we would think not so much of the growth of NATURE as of the advance which in the last twenty years it has chronicled.

A formal history of science for that period would be a formidable task, but it is already possible to discern what will probably appear to posterity to be the most salient characteristics of the last two decades.

In the physical sciences, the enormous development of the atomic theory, and the establishment of a connection between the theories of electricity and light, are perhaps the two main achievements of the years we are considering. Methods of accomplishing the at first sight impossible task of measuring atomic magnitudes have been devised. Our own volumes contain some of the most interesting papers of Sir William Thomson on this subject, and the close agreement in the results attained by very different methods is sufficient proof that, if only approximations, they are approximations we may trust. The brilliant vortex atom theory of Sir William Thomson has not as yet achieved the position of a proved hypothesis, but has stimulated mathematical inquiry. A number of very powerful researches have added to our knowledge of a most difficult branch of mathematics, which may yet furnish the basis of a theory which shall deduce the nature of matter and the phenomena of radiation from a single group of assumptions.

The theory of gases has been extended in both direc-

tions. The able attempt of Van der Waals to bring both vapour and liquid within the grasp of a single theory is complementary to the extension by Crookes, Hittorf, and Osborne Reynolds of our knowledge of phenomena which are best studied in gases of great tenuity.

The gradual expansion of thermodynamics, and in general of the domain of dynamics from molar to molecular phenomena, has been carried on by Willard Gibbs, J. J. Thomson, and others, until, in many cases, theory seems to have outrun not only our present experimental powers, but almost any conceivable extension which they may hereafter undergo.

The pregnant suggestion of Maxwell that light is an electro-magnetic phenomenon has borne good fruit. Gradually the theory is taking form and shape, and the epoch-making experiments of Hertz, together with the recent work of Lodge, J. J. Thomson, and Glazebrook, furnish a complete proof of its fundamental hypotheses. The great development of the technical applications of electricity has stimulated the public interest in this science, and has necessitated a more detailed study of magnetism and of the laws of periodic currents. The telephone and the microphone have eclipsed the wonders of the telegraph, and furnish new means of wresting fresh secrets from Nature.

Science has become more than ever cosmopolitan, owing chiefly to the imperative necessity for an early agreement as to the values of various units for a common nomenclature, and for simultaneous observations in widely separated localities. International Conferences are the order of the day, and the new units which they have defined are based upon experiments by many first-rate observers in many lands, amongst whom the name of Lord Rayleigh stands second to none.

On the side of chemistry the periodic law of Mendeleeff has become established as a generalization of the first importance, and the extraordinary feat of foretelling the physical properties of an as yet undiscovered element has attracted to it the attention of the whole scientific world.

The once permanent gases are permanent no more. Dulong and Petit's law has found a complement in the methods of Raoult. The old doctrine of valency is giving way to more elastic hypotheses. The extraordinary progress of organic chemistry, which originated in the work and influence of Liebig and the Giessen school, has continued at an accelerated rate. The practical value of even the most recondite investigations of pure science has again been exemplified by the enormous development of the coal-tar industry, and by the numerous syntheses of organic products which have added to the material resources of the community.

The increase of our knowledge of the sun by means of localized spectroscopic observation, the application of photography to astronomy, and more recently still the extension and generalization of the nebular hypothesis are perhaps the most remarkable developments of those branches of science which relate to astronomy. Stars which no human eye will ever see are now known to us as surely as those which are clearly visible. The efforts to reduce nebulæ, comets, and stars under one common law, as various cases of the collision or aggregation of meteoritic swarms, and the striking investigations of Prof. Darwin on the effects of tidal action, and on the application of the laws of gases to a meteoritic plenum, give promise of a fuller knowledge of the birth and death of worlds.

In the biological sciences, the progress during the last twenty years has consisted chiefly in the firm establishment of the Darwinian doctrine, and the application of it and its subordinate conceptions in a variety of fields of investigation. The progress of experimental physiology has been marked by increasing exactitude in the application of physical methods to the study of the properties of living bodies, but it has not as yet benefited, as have other branches of biology, from the fecundating influence of Darwin's writings: hence there is no very prominent physiological discovery to be recorded. The generation of scientific men which is now coming to middle age has been brought up in familiarity with Mr. Darwin's teaching, and is not affected by anything like hostility or *a priori* antagonism to such views. The result is seen in the vast number of embryological researches (stimulated by the theory that the development of the individual is an epitome of the development of the race) which these twenty years have produced, and in the daily increasing attention to that study of the organism as a living thing definitely related to its conditions which Darwin himself set on foot. The marine laboratories of Naples, Newport, Beaufort, and Plymouth, have come into existence (as in earlier years their forerunners on the coast of France), and served to organize and facilitate the study of living plants and animals. The *Challenger* and other deep-sea exploring expeditions have sailed forth and returned with their booty, which has been described with a detail and precision unknown in former times. The precise methods of microscopic study by means of section-cutting—due originally to Stricker, of Vienna—have within these twenty years made the study of cell-structure and cell-activity as essential a part of morphology as it had already become of physiology. These, and the frank adoption of the theory of descent, have swept away old ideas of classification and affinities, and have relegated the Ascidian "polyps" of old days to the group of Vertebrata, and the Sponges to the Cœlenterates. The nucleus of the protoplasmic cell —which twenty years ago had fallen from the high position of importance accorded to it by Schwann—has, through the researches of Bütschli, Flemming, and Van Beneden, been reinstated, and is now shown to be the seat of all-important activities in connection with cell-division and the fertilization of the egg. The discovery of

the phenomena of karyokinesis and their relation to fertilization will be reckoned hereafter as one of the most, if not the most, important of the biological discoveries of the past twenty years.

Apart from Darwinism, the most remarkable development of biological studies during these "twice ten tedious years" is undoubtedly the sudden rise and gigantic progress of our knowledge of the Bacteria. Though the foundations were laid fifty years ago by Schwann and Henle, and great advances were made by Pasteur and by Lister just before our period, yet it is within this span that the microscope and precise methods of culture have been applied to the study of the "vibrions," or "microbes," and the so-called "bacteriology" established. We now know, through the labours of Toussaint, Chauveau, Pasteur, and Koch, of a number of diseases which are definitely caused by Bacteria. We also have learnt from Pasteur how to control the attack of some of these dangerous parasites. Within these twenty years the antiseptic surgery founded by Sir Joseph Lister has received its full measure of trial and confirmation, whilst his opportunities and those of his fellow-countrymen for making further discovery of a like kind have been ignorantly destroyed by an Act of Parliament.

To particularize some of the more striking zoological discoveries which come within our twenty years, we may cite—the Dipnoous fish-like creature *Ceratodus* of the Queensland rivers, discovered by Krefft; the jumping wheel-animalcule *Pedalion*, of Hudson; the development and the anatomy of the archaic Arthropod Peripatus worked out by Moseley, Balfour, and Sedgwick; the Hydrocorallinæ of Moseley, an entirely new group of compound animals; the fresh-water jelly-fish *Limnocodium* of the Regent's Park lily-tank; the Silurian scorpion of Gotland and Lanarkshire; the protozoon Chlamydomyxa discovered by Archer in the Irish bogs; the Odontornithes and the Dinocerata of the American palæontologists; the intracellular digestion obtaining in animals higher than Protozoa, and the significance of the "diapedesis" of blood-corpuscles in inflammation, and the general theory of phagocytes due to Mecznikow; the establishment of the principle of degeneration as of equal generality with that of progressive development, by Anton Dohrn; the demonstration by Weismann and others that we have no right to mix our Darwinism with Larmarckism, since no one has been able to bring forward a single case of the transmission of acquired characters. Perhaps the attempt to purify the Darwinian doctrine from Lamarckian assumption will hereafter be regarded—whether it be successful or not—as the most characteristic feature of biological movement at the end of our double decade Its earlier portion was distinguished by the publication of some of Darwin's later works. Its greatest event was his death.

In botany, twenty years ago, the teaching in our Universities was practically sterile. In one of our earliest numbers, Prof. James Stewart defended with some vigour the propriety of intrusting botany to a lecturer at Cambridge who was also charged with the duty of lecturing on electricity and magnetism. It is startling to compare a past, in which botany was regarded as a subject which might be tacked on anywhere, with its present condition, in which there is scarcely a seat of learning in the three kingdoms which is not turning out serious work. The younger English school would be ungrateful if it did not acknowledge its debt to the eminent German teachers from whom it has derived so much in the tradition and method of investigation. Sachs and De Bary have left an indelible mark on our younger Professors. But it would be a mistake to suppose that English modern botany has simply derived from Germany. It has developed a character of its own, in which the indirect influence of Darwin's later work can be not indistinctly traced. There has been a gradual revolt in England, the ultimate consequences of which have still to be developed, against the too physical conception of the phenomena of plant life which has been prevalent on the Continent. Darwin, by his researches on insectivorous plants and plant movements from a purely biological point of view, prepared the way for this; Gardiner followed with a masterly demonstration of the physical continuity of protoplasm in plant tissues. This has thrown a new light on the phenomena studied by Darwin, and we need not, therefore, be surprised that his son, F. Darwin, has started what is virtually a new conception of the process of growth, by showing that its controlling element is to be sought in the living protoplasm of the cell, rather than in the investing cell-wall. On the whole, English botanists have shown a marked disposition to see in the study of protoplasm the real key to the interpretation of the phenomena of plant life. The complete analogy between the processes of secretion in animals and vegetables, established by Gardiner, and the essential part played by ferments in vegetable nutrition, illustrated by Green, are examples of the results of this line of inquiry. To Germany we owe a flood of information as to the function of the cell-nucleus, which it is singular has met with general acceptance but little detailed corroboration in this country.

In morphology a review would be ineffective which did not go somewhat deeply into detail. The splendid hypothesis of Schwendener, of the composite nature of lichens as a commensal union of Algæ and Fungi, has gradually won its way into acceptance. In England there is little of the first rank which calls for note except the researches of Bower on the production of sexual organs on the leafy plant in ferns without the intervention of an intermediate generation.

In vegetable physiology there seems a pause; the

purely physical line of inquiry, as already suggested, seems to have yielded its utmost. The more biological line of inquiry has only yet begun to yield a foretaste of the results which will undoubtedly ultimately flow from it.

Something must be added as to systematic and geographical botany. The "Genera Plantarum" of Bentham and Hooker, the work of a quarter of a century at Kew, affords a complete review of the higher vegetation of the world, and has been accepted generally as a standard authority. To Bentham also we owe the completion of the "Flora Australiensis," the first complete account of the flora of any great continent.

In geographical botany, perhaps the most interesting results have been the gradual elaboration of a theory as to the distribution of plants in Africa, and the botanical exploration of China, of the vegetable productions of which, twenty years ago, almost nothing was known.

In the classification of the lower plants, perhaps the most interesting result has been the happy observations of Lankester upon a coloured Bacterium, which enabled him to show that many forms previously believed to be distinct might be phases of the same life-history.

In geology probably the greatest advance has been in the application of the microscope to the investigation of rock structure, which has given rise to a really rational petrology. All except the coarser-grained rocks were only capable of being described in vague terms; with modern methods their crystalline constituents are determinable, however minute, and the conditions under which they were formed can be inferred.

It is, impossible, even in a brief review of this kind, to think only of what has been won, and to ignore the loss of leaders who were once foremost in the fray. In England three names which will never be forgotten have been removed from the muster-roll. Darwin, Joule, and Maxwell can hardly be at once replaced by successors of equal eminence. As the need arises, however, men will no doubt be found adequate to the emergency, and it is at least satisfactory to know that they will appeal to a public more capable than heretofore of appreciating their efforts.

The support afforded by the Governments of Western Europe to scientific investigation has been markedly increased within the period which we survey. France has largely extended her subsidies to scientific research, whilst Germany has made use of a large part of her increased Imperial revenue to improve the arrangements for similar objects existing in her Universities. The British Government has shown a decided inclination in the same direction: the grant to the Royal Society for the promotion of scientific research has been increased from £1000 to £4000 a year; whilst subsidies have been voted to the Marine Laboratory at Plymouth, to the Committee on Solar Physics, to the Meteorological Council, and quite recently to the University Colleges throughout the country, of which last it is to be hoped that a fair proportion will be devoted to the promotion of research rather than to the reduction of class fees.

Twenty years ago England was in the birth-throes of a national system of primary instruction. This year has seen the State recognition of the necessity of a secondary and essentially a scientific system of education, and the Technical Instruction Act marks an era in the scientific annals of the nation.

The extension of scientific teaching has gone on rapidly within and without our Universities. Twenty years ago the Clarendon Laboratory at Oxford was approaching completion, and was the only laboratory in the country which was specially designed for physical work. Now, not only has Cambridge also its Cavendish Laboratory, but both Universities have rebuilt their chemical laboratories, both have erected buildings devoted to the study of biology, and the instruction of students in both zoology and botany has taken a characteristic practical form which we owe to the system of concentrating attention on a series of selected "types" introduced by Rolleston and by Huxley. Oxford has been furnished with an astronomical observatory by the liberality of Warren De la Rue, and Cambridge has accepted the noble gift of the Newall telescope. Nor have such proofs of the vitality of science been confined to the Universities.

Twenty years ago the Owens College was a unique institution: now, united with two thriving Colleges in Leeds and Liverpool, it forms the Victoria University; while science is studied in appropriate buildings in Birmingham, Newcastle, Nottingham, and half a dozen towns beside.

A race is thus springing up which has sufficient knowledge of science to enforce due recognition of its importance, and public opinion can now, far more than in the past, be relied on to support its demands. Fortunately, too, these can be authoritatively expressed. The Royal Society wields, if it chooses to exercise it, an enormous power for good. Admitted on all hands to be the supreme scientific authority in this country, its decisions are accepted with a deference which can spring only from respect for the knowledge and scrupulous fairness by which they are dictated. If sometimes it moves slowly, *pur se muove*, and it is delightful to turn from the babble of the politicians to the study of an institution which does its work well, and perhaps too noiselessly. But even the House of Commons, hitherto ignorant and therefore apathetic in matters scientific, is awakening to the fact that there are forces to be reckoned with and impulses to be stimulated and controlled which are of more enduring import to the national welfare than mere party politics. And the people, too, are beginning to see that it is to the economic working of these forces, and to the right direction of these impulses, that their representatives are bound to give attention. True it is that

another generation may possibly pass away before either the House of Commons or even Ministers are sufficiently instructed in science to recognize fully their responsibility in this direction.

Whatever, then, the future may bring, the last twenty years have been characterized by progress both steady and rapid. The tide flows on with no sign of check, and we accept the success of NATURE in no spirit of self-gratulation, but as a straw by which the speed of the current may be gauged.

MODERN VIEWS OF ELECTRICITY.

Modern Views of Electricity. By Oliver J. Lodge, D.Sc., LL.D, F.R.S. (London: Macmillan and Co., 1889.)

IN this interesting book Prof. Lodge gives a very lively and graphic account of many of the most recent speculations about the nature of electrical phenomena. A work with this object was urgently needed, as the method of regarding these phenomena given in popular treatises on electricity is totally different from that used by those engaged in developing the subject.

The attention called by Faraday and Maxwell to the effects produced by and in the medium separating electrified bodies has had the effect of diverting attention from the condition of the charged bodies in the electric field to that of the medium separating them, and it is perhaps open to question whether this of late years has not been too much the case. To explain the effects observed in the electric field we should require to know the condition not only of the ether, but also of the conductors and insulators present in it; just as a complete theory of light would include the state of the luminous bodies as well as of the ether transmitting the radiations excited by them. Since matter is more amenable to experiment than the ether, it seems most probable that we shall first gain an insight into the nature of electricity from a study of those cases where matter seems to play the chief part—such as in the electric discharge through gases, and the phenomena of electrolysis—rather than from speculations, however interesting, as to what takes place in the ether when it is transmitting electrical vibrations. Prof. Lodge, however, in the work under consideration, devotes most of his space to the consideration of the ether. In his preface he says, "Few things in physical science appear to me more certain than that what has so long been called electricity is a form, or rather a mode, of manifestation of the ether;" and he proceeds to give precision to this somewhat vague statement by developing a theory that electricity is a fluid, and a constituent of a very complex ether. In the first few chapters he supposes that all insulators, including the ether, have a cellular structure the cells being filled with a fluid which is electricity, and which is not able to get from one cell to another unless the walls of the cells are broken down; in conductors, however, there are channels between the cells, so that the electricity is able to flow more or less freely through them. A flow of this fluid is an electric current. But if this is the case, anything which sets the ether in motion will produce an electric current. Now, Fizeau's experiments show that moving bodies carry the ether with them to an extent depending on their index of refraction; so that a disk made of glass or other refracting substance, if set in rapid rotation about an axis through its centre, and at right angles to its plane, ought to act as if currents were circulating in the disk, and produce a magnetic field around it. In order to avoid the allied difficulty that nothing has ever been observed which indicates that a magnet or a current flowing through a coil possesses gyroscopic properties, Prof. Lodge assumes, in subsequent chapters, that the fluid in the cells of the ether is a mixture of two fluids, and that these two fluids are positive and negative electricity: and that, in order to exhibit any electrical effect, the compound fluid has first to be decomposed into positive and negative electricity by the application of an electromotive force. A current of electricity, on this view, consists of the flow of equal quantities of positive and negative electricity in opposite directions. Thus this, the most "modern view of electricity," is in its most important features almost identical with the old two-fluid theory published by Symmer in 1759. We confess we do not think the theory in its present form advances the science of electricity much: it does not suggest new phenomena, nor does it lend itself readily to explain the action of matter in modifying electrical phenomena; it demands, too, a very artificial ether. It would seem that the first steps required to make a theory of this kind a real advance on the old two-fluid theory would be the discovery of a structure for the ether, which would possess the same kind of properties as the mixture of the two electricities on that theory. A great deal, too, is left indefinite in the theory: thus, for example, we are not told whether for a given current these streams are moving slowly or with prodigious velocities. In fact, there is throughout the book rather a want of definite conclusions, and this is rather hidden by the vigorous style in which Prof. Lodge writes: he develops his ideas in such an enthusiastic and interesting way that on the first reading they seem to be a good deal more definite than they prove to be on calmer reflection.

But whatever may be thought of Prof. Lodge's theory of electricity, there can be, we think, no two opinions of the value of the numerous models illustrating the properties of electrical systems which he has invented. These must prove of the greatest assistance in enabling the student to gain a clear and vivid idea of electrical processes, and ought to be largely employed by all teachers of electricity.

In a work dealing so briefly with such a multitude of different and difficult subjects it is natural that there should be many statements to which exception might be taken. Prof. Lodge disarms criticism by his frank admission of this; sometimes, also, by an amusing vagueness of statement: thus, on p. 206, in speaking of the condition of the ether inside a strongly-magnetizable substance, he says: "Perhaps it is that the atoms themselves revolve with the electricity; perhaps it is something quite different." There are, however, some statements of a less theoretical kind which seem to us likely to mislead the student. Thus it is stated that the amount of the Peltier effect shows that the difference of potential between zinc and copper is only a few micro-volts. The Peltier effect, however, without further assumption, cannot tell us anything about the absolute magnitude of the difference of

potential between the metals; it can only give us the value of the temperature coefficient, which is equal to the Peltier effect divided by the absolute temperature. Then, again, the pyro-electricity of tourmaline is explained by the unilateral conductivity of a tourmaline crystal whose temperature is changing, discovered by the author and Prof. Silvanus Thompson. If this unilateral conductivity is regarded as proving the existence of an electromotive force in a crystal which is increasing or decreasing in temperature, the explanation is valid, but in the text nothing is said about an electromotive force, and the student might be led to infer that a mere difference in resistance could explain pyro-electricity. The way in which a current flows past an insulating obstacle, the lines of flow closing in on the obstacle, and leaving nothing corresponding to "dead water" behind it, is given as a proof that the electric current has no mechanical momentum; but unless the corners of the obstacle were infinitely sharp, a slowly-moving fluid might flow in the same way as electricity, even though it possessed inertia, so that the proof is not conclusive. It is also stated that the effects on light produced by a magnetized body, discovered by Dr. Kerr, of Glasgow, have been deduced by Prof. Fitzgerald from Maxwell's theory of light. As a matter of fact, however, the results deduced from this theory by Fitzgerald do not coincide with those observed by Dr. Kerr and Prof. Kundt. The production in an unequally-heated conductor of an electromotive force is explained by supposing the atoms in such a body to be moving faster in one direction than the opposite, and therefore, since they are supposed to drag the ether with them, producing a flow of ether in the direction in which they are moving fastest; but, on the dualistic theory of electricity adopted in this book, this ether stream would consist of equal quantities of positive and negative electricity moving in the *same* direction, and this would not produce any electrical effect.

At the end of the book are three popular lectures delivered by Prof. Lodge, the first on the relation between electricity and light, the second on the ether and its functions, and the third his admirable one at the Royal Institution, on the discharge of a Leyden jar, which is a model of what such a lecture ought to be.

Taken as a whole, we think that the book is one which ought to be read by all advanced students of electricity; they will get from it many of the views which are guiding those who are endeavouring to advance that science, and it is so stimulating that no one can read it without being inspired with a desire to work at the subject to which it is devoted.

THE CALCULUS OF PROBABILITIES.

Calcul des Probabilités. Par J. Bertrand. (Paris: Gauthier-Villars, 1889.)

"EVERYBODY makes errors in Probabilities at times, and big ones," writes De Morgan to Sir William Hamilton. M. Bertrand appears to form an exception to this dictum, or at least to its severer clause. He avoids those slips in the philosophical part of the subject into which the greatest of his mathematical predecessors have fallen. Thus he points out that, in investigating the "causes" of an observed event, or the ways in which it might have happened, by means of the calculus of probabilities, it is usual to make certain unwarranted assumptions concerning the so-called *a priori* probability of those causes. Suppose that a number of black and white balls have been drawn at random from an urn, and from this datum let us seek to determine the proportion of black and white balls in the urn. It is usual to assume, without sufficient grounds, that *a priori* one proportion of balls, one constitution of the urn, is as likely as another. Or suppose a coin has been tossed up a number of times, and from the observed proportion of heads and tails let it be required to determine whether and in what degree the coin is loaded. Some assumption must be made as to the probability which, prior to, or abstracting from, our observations, attaches to different degrees of loading. The assumptions which are usually made have a fallacious character of precision.

Again, M. Bertrand points out that the analogy of urns and dice has been employed somewhat recklessly by Laplace and Poisson. It is true that the ratio of male to female births has a constancy such as the statistics of games of chance present. But, before we compare boys and girls to black and white balls taken out at random from an urn, we must attend not only to the average proportion of male to female births, but also to the deviations from that average which from time to time or from place to place may be observed. The analogy of urns and balls is more decidedly inappropriate when it is applied to determine the probable correctness of judicial decisions. The independence of the judges or jurymen which the theory supposes does not exist.

> "Quand un juge se trompe il y a pour cela des raisons: il n'a pas réellement mis la main dans une urne où le hazard l'a mal servi. Il a ajouté foi à une faux témoignage, le concours fortuit de plusieurs circonstances a éveillé à tort sa défiance, un avocat trop habile l'a ému, de hautes influences peutêtre l'ont ébranlé. Ses collègues ont entendu les mêmes témoins, on les a instruits des mêmes circonstances, le même avocat a plaidé devant eux, on a tenté sur eux la même pression."

With equal force does M. Bertrand expose the futility of the received reasoning by which it is pretended to determine the probability that the sun will rise to-morrow from the fact that it has risen so many days in the past.

These reflections are just and important; but their value is somewhat diminished by the fact that they have been, for the most part, made by previous writers with whom our author seems unacquainted. Thus Prof. Lexis has more carefully considered the extent of the error committed by Laplace and Poisson in applying to male and female births and other statistics rules derived from games of chance. The fundamental principles of Probabilities have been more fully explored by Dr. Venn. M. Bertrand, like Laplace, starts by defining the probability of an event as the ratio of the number of favourable cases to the number of possible cases. He does not explain what constitutes a "favourable case"—that, when a die is thrown, the probability of obtaining the 3 or 4 is one-sixth, because as a matter of fact each side in the long run turns up once out of six times. Accordingly, when he argues that in a great number of trials each event is most likely to occur with a frequency correspond-

ing to its probability, he lays himself open to the charge of circularity which Dr. Venn has brought against Bernouilli's theorem. Without pronouncing on this delicate question, we may safely say, with respect to the first principles of the subject, that no point which has been left obscure by Dr. Venn has been cleared up by M. Bertrand.

It is with respect to the purely mathematical portion of the calculus, or that part of its metaphysics which is inextricably mixed with mathematics, that we expected and have found most assistance from M. Bertrand. Hitherto the study of Probabilities has been barred by the dilemma which M. Bertrand thus states:—

"On ne peut bien connaître le calcul des probabilités sans avoir lu le livre de Laplace; on ne peut lire le livre de Laplace sans s'y préparer par les études mathématiques les plus profondes."

Much of Laplace's analysis which must have affected many eager students like stickjaw has been simplified by M. Bertrand. He is in general more readable than Poisson. Several of the theorems which he gives seem to be new. His methods of determining from a given set of observations the characteristic, or *modulus*, appertaining to the source of error are specially interesting.

M. Bertrand's mathematical power enables him to carry the torch of common-sense to those perplexed parts of the subject where less qualified critics, awed by the imposing mass of symbols, have hesitated to differ from Laplace or Poisson. Of this kind is the simultaneous determination of several quantities from a great number of equations. When Laplace computes that the odds are a million to one against the occurrence of an error of assigned magnitude in the determination of Jupiter's mass, M. Bertrand shows reasons for suspecting the accuracy of such computations. In fact, he carries out Poinsot's witty direction:

"Après avoir calculé la probabilité d'une erreur il faudrait calculer la probabilité d'une erreur dans le calcul."

The true import and proper application of the theory of errors of observation are thus well expressed:—

"On peut accepter sans crainte le résultat, mais il est téméraire d'évaluer en chiffres la confiance qu'il doit inspirer."

M. Bertrand teaches with authority—and not like those who have not followed the higher mathematical reasonings of the calculus—in what spirit its conclusions should be accepted.

Still, even with regard to those parts of the subject where a first-rate mathematician has so great an advantage, we venture to think that the work would have been much more valuable if the writer had taken the trouble to acquaint himself more fully with what his predecessors had done. For example, in discussing the reasons for taking the arithmetic mean of a set of observations (presumed to be equally good) relating to a single quantity, M. Bertrand does not dwell on the argument that the probability-curve —with which the arithmetic mean is specially correlated—is apt to represent the grouping of errors for this reason, that an error may be regarded as a function of a great number of elements each obeying some definite law of facility, and that the values of such a function conform to the probability-curve. It is true that Laplace, from whom this argument may be derived, has not himself used it very directly. But in a writer on the method of least squares we may expect some conversance with more recent works, in particular with Mr. Glaisher's classical paper in the Memoirs of the Astronomical Society (London). Moreover, Laplace does employ the mathematical theorem which we have indicated, not indeed to prove that the law of facility for errors of observation in general is the probability-curve, but that, whatever that law of facility be, the most advantageous combination is a certain linear function. A treatise in which this celebrated argument is not discussed cannot be regarded as exhaustive. But it is remarkable that with respect to the combination of observations, M. Bertrand seems to defer more to Gauss than to his own eminent countryman.

M. Bertrand has indeed slipped in a doctrine for which the authority of Laplace may be quoted, that in choosing the best combination of a set of observations "there is an essential difference between the most probable value of a quantity and the value which it is best to adopt" (Bertrand, Art. 138); the latter being the mean (first power) of the observations (Art. 155)—which M. Bertrand rather awkwardly terms "la valeur probable." M. Bertrand does not seem to realize the gravity of the assumption which is contained in the latter clause. Later on he employs Gauss's criterion of erroneousness—namely, the mean square of error. But the ground, nature, and relation of these two principles are not very clearly explained by the writer. With respect to the philosophical foundation of the method of least squares he has not superseded the necessity of studying Laplace.

With these reservations, M. Bertrand's work may be regarded as one of the most complete treatises on the subject. Nowhere else are the two elements so peculiarly combined in the science of Probabilities—commonsense and mathematical reasoning—to be found existing together in such abundance. F. Y. E.

ARGENTINE ORNITHOLOGY.

Argentine Ornithology. By P. L. Sclater, Ph.D., F.R.S., and W. H. Hudson, C.M.Z.S. Vol. II. (London: W. H. Porter, 1889.)

THE completion of this important work is an event of considerable importance to every lover of neotropical zoology, and the authors have both performed their parts well, while the ten plates by Mr. Keulemans are beautifully drawn and admirably coloured. Among the increasing number of Englishmen who settle in the Argentine Republic, there are sure to be many who will pursue natural history studies, and to all such a well-executed book like the present will be invaluable. The joint authors of the work are happy in their association, for while Dr. Sclater brings to the work a vast experience, and a sound scientific knowledge of his subject, it is certain that never was there a better describer of the habits of birds than Mr. Hudson. Although of English parentage, he is a native-born Argentine, and he has grown up among the birds whose life and history he so well knows how to portray. In turning over the pages of this volume, we have found many interesting extracts which we should have liked to present to our readers,

and we feel that we should not be doing justice to Mr. Hudson if we did not quote for their benefit one specimen of this naturalist's writing. He is describing the habits of the Carancho (*Polyborus tharus*):—

"When several of these birds combine they are very bold. A friend told me that while voyaging on the Paraná River a black-necked Swan flew past him hotly pursued by three Caranchos; and I also witnessed an attack by four birds on a widely different species. I was standing on the bank of a stream on the Pampas watching a great concourse of birds of several kinds on the opposite shore, where the carcass of a horse, from which the hide had been stripped, lay at the edge of the water. One or two hundred Hooded Gulls and about a dozen Chimangos were gathered about the carcass, and close to them a very large flock of Glossy Ibises were wading about in the water, while amongst these, standing motionless in the water, was one solitary white Egret. Presently four Caranchos appeared, two adults and two young birds in brown plumage, and alighted on the ground near the carcass. The young birds advanced at once and began tearing at the flesh; while the two old birds stayed where they had alighted, as if disinclined to feed on half-putrid meat. Presently one of them sprang into the air and made a dash at the birds in the water, and instantly all the birds in the place rose into the air screaming loudly, the two young brown Caranchos only remaining on the ground. For a few moments I was in ignorance of the meaning of all this turmoil, when, suddenly, out of the confused black and white cloud of birds the Egret appeared, mounting vertically upwards with vigorous measured strokes. A moment later, and first one, then the other, Carancho also emerged from the cloud, evidently pursuing the Egret, and only then the two brown birds sprang into the air and joined in the chase. For some minutes I watched the four birds toiling upwards with a wild zigzag flight, while the Egret, still rising vertically, seemed to leave them hopelessly far behind. But before long they reached and passed it, and each bird as he did so would turn and rush downwards, striking at the Egret with his claws, and while one descended the others were rising, bird following bird with the greatest regularity. In this way they continued toiling upwards until the egret appeared a mere white speck in the sky, about which the four hateful black spots were still revolving. I had watched them from the first with the greatest excitement, and now began to fear that they would pass from sight and leave me in ignorance of the result; but at length they began to descend, and then it looked as if the Egret had lost all hope, for it was dropping very rapidly, while the four birds were all close to it striking at it every three or four seconds. The descent for the last half of the distance was exceedingly rapid, and the birds would have come down almost at the very spot they started from, which was about forty yards from where I stood, but the Egret was driven aside, and sloping rapidly down struck the earth at a distance of two hundred and fifty yards from the starting point. Scarcely had it touched the ground before the hungry quartette were tearing it with their beaks. They were all equally hungry no doubt, and perhaps the old birds were even hungrier than their young; and I am quite sure that if the flesh of the dead horse had not been so far advanced towards putrefaction they would not have attempted the conquest of the Egret. I have so frequently seen a pure white bird singled out for attack in this way, that it has always been a great subject of wonder to me how the two common species of snow-white Herons in South America are able to maintain their existence; for their whiteness exceeds that of other white waterfowl, while, compared with Swans, Storks, and the Wood-ibis, they are small and feeble. I am sure that if these four Caranchos had attacked a Glossy Ibis they would have found it an easier conquest; yet they singled out the egret, purely, I believe, on account of its shining white conspicuous plumage."

In his introduction Dr. Sclater gives a *résumé* of the number of genera and species inhabiting the Argentine Republic, and shows that the avifauna of that portion of South America belongs to the Patagonian sub-region. A little sketch-map would have been useful, to show the configuration of the country and the proportions of the mountain-ranges, as it is evident that a district which can boast of a Dipper, and be at the same time the home of two Cariamas, must possess elements of two very different avifaunæ. Some day, no doubt, an exact exploration, such as that now being undertaken in Mexico by Messrs. Salvin and Godman, will trace the limits of the avifaunæ of the Pampas and the mountain regions. If Mr. Hudson could only be induced to resume his work of exploration and visit the interior of the Argentine Republic, the results would be, we venture to say, of the first importance to science.

Dr. Sclater, we notice, draws his comparisons of the different orders of Argentine birds from the "Nomenclator Avium Neotropicalium" of 1873, which is rather ancient history. The statistics of American birds must have altered considerably since that date, if we may judge from the Tanagers alone, which numbered 302 species in 1873, and in 1886 had reached 377 in number, according to Dr. Sclater's own estimate. In dividing the Neotropical Region into the sub-regions he adopts the conclusions of Prof. Newton in the "Encyclopædia Britannica," but the names of one or two of them are changed. The boundaries seem to be extremely natural, according to our present state of knowledge, though we would scarcely consider the Central American sub-region (or the Transpanamic sub-region, as Dr. Sclater renames it) to be bounded on the north by Tehuantepec! The author probably intended to give only a general outline, for the northern boundaries of the Central American sub-region are much more elaborately defined in fact.

R. BOWDLER SHARPE.

OUR BOOK SHELF.

The Chemistry of the Coal-tar Colours. From the German of Dr. R. Benedikt. Translated, with Additions, by Dr. E. Knecht. Second Edition. (London: George Bell and Sons, 1889.)

DR. BENEDIKT'S little book is a standard treatise in Germany, where the literature of the coal-tar colours is fast becoming a most important branch of the general literature of applied chemistry; and Dr. Knecht has done excellent service in making the work more generally known to English readers by means of his translation. It is remarkable that, although England may be said to have originated the coal-tar colour industry, she has contributed comparatively little to the general literature of the subject. Practically, all the systematized information we possess has come to us through the medium of French and German manuals. A number of our chemists could be named who have communicated original memoirs on the constitution of organic colouring-matters to the recognized organs of chemical research, but their work is very special in its character, and appeals rather to the pure chemist than to the technologist, and hence is seldom read by the latter. The want of a good, sound, and comprehensive treatise on the subject

of the coal-tar colour industry has, we think, not been without its influence on the development of this branch of applied organic chemistry in this country. Dr. Knecht's translation merits a place on the bookshelf of every person engaged in the manufacture and use of the so-called coal-tar colours.

A Bibliography of Geodesy. By J. Howard Gore, B.S., Ph.D. (Washington: Government Printing Office, 1889.)

THIS valuable work forms Appendix No. 16 to the 1887 Report of the United States Coast and Geodetic Survey and is another example of the disinterested energy displayed by our Transatlantic cousins in scientific matters. With great perseverance, and at the cost of much time and trouble, Mr. Gore personally explored thirty-four of the principal libraries of America and Europe, and numerous minor libraries by proxy; and, in addition, he checked and completed many of his references by correspondence with the living authors of both continents. The extent of his labours is shown by the four hundred columns of references, and short remarks where the title alone is not sufficiently explanatory. An alphabetical arrangement is adopted, and this includes authors, abbreviations, and subjects.

It is gratifying to note that our own country, besides the assistance rendered by its libraries, lends its aid to such an important work in the shape of a manuscript supplement by Colonel Herschel to his pendulum bibliography, which was placed unreservedly at Mr. Gore's disposal, through the courtesy of the Royal Society. After the offers of publication made by various institutions, including the International Geodetic Association at Berlin, no further testimony to Mr. Gore's fitness for the work is needed, and the compiler is justly proud "to see the results of his labours issuing from an institution of his own country, which throughout the world is the recognized advance guard in geodetic science."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Method of Quarter Squares.

I OMITTED any reference to Leslie in my review of Mr. Blater's table (NATURE, vol. xl. p. 573), as I have never supposed that he was an independent discoverer of the method, or an independent calculator of a table, of quarter squares. I have referred to his table in my Report on Mathematical Tables Brit. Assoc. Report, 1873, p. 23); and the passage quoted by Prof. Carey Foster (p. 593) is given in full in the preface to Mr. Blater's table. It seems to me that the words in question—"This application of a table of quarter squares, as it is derived from the simplest principles, might have readily occurred to a mathematician; yet I have nowhere seen it brought into practical use till, last summer, I met with, at Paris, a small book by Antoine Voisin, printed in 1817"—do not indicate an independent discovery; and this view is confirmed by the fact that, in the first edition of the "Philosophy of Arithmetic" (1817), Leslie makes no mention of quarter squares. It was only in the second edition (1820), after having seen Voisin's work in the previous year, that he added, at the end of the volume, an account of the method, and a table extending to 2000. The table was copied, I presume, from Voisin, as Leslie does not claim it as the result of his own calculation. In the British Association Report I have described it as "reprinted from Voisin," and have pointed out that it did not appear in the first edition. In the preface to Mr. Blater's letter it is described as "an extract from Voisin's table." Although we may, I think, infer, almost with certainty, that the table is only a reprint,[1] it is to be regretted that Leslie did not say so explicitly.

J. W. L. GLAISHER.

Trinity College, Cambridge, October 26.

[1] After quoting the full title of Voisin's table, Leslie refers to his own table as "the specimen which I have given."

Darwinism.

MR. ROMANES states that it is "absurd" to call his essay on physiological selection an elaborate (I said "laborious") attack upon Mr. Darwin's theory of the origin of species. In that essay I find these words (p. 345), "the theory of natural selection has been misnamed: it is not strictly speaking a theory of the origin of species"; and on p. 403, "the theory of physiological selection [*i.e.* Dr. Romanes's theory] has this advantage over every other theory that has ever been propounded on the origin of species"; and again, "the problem of the origin of species which, as shown in the preceding paper [viz. the laborious essay], his [Mr. Darwin's] theory of natural selection serves only in small part to explain."

On the other hand, Mr. Darwin entitled his great work, "The Origin of Species by means of Natural Selection, or the preservation of favoured races in the struggle for life." He considered his theory of natural selection to be a theory of the origin of species. Mr. Romanes says it is not. I say that this is an attack on Mr. Darwin's theory, and about as simple and direct an attack as possible. Why Mr. Romanes wishes us to believe that he did not attack Mr. Darwin's theory it is difficult to conceive. That he should hope to persuade anyone that it is absurd to call his essay an attack on Mr. Darwin's theory when this is what it distinctly professes to be is curious. I trust you will not permit an empty discussion on this matter, but leave it to your readers to find out by reference to the Proc. Linn. Soc., vol. xix., where the absurdity exists.

Record of British Earthquakes.

WILL you allow me to ask your readers to help me in compiling notes of the earthquakes felt in this country during the present and following years?

Mr. Mallet's great Catalogue of all recorded earthquakes ends, as is well known, with the year 1842. Previously to this, Mr. David Milne had published a series of papers on the earthquakes of Great Britain in the *Edinburgh New Philosophical Journal* (vols. xxxi. to xxxvi. for the years 1841-44). These papers, which are of very great value, bring down our record to the end of August 1843. In recent years we have had the Catalogues of Prof. J. P. O'Reilly (Trans. Roy. Irish Acad., vol. xxviii. pp. 285-316 and 489-708) and the late Mr. W. Roper (published by T. Bell, *Observer* Office, Lancaster). The latter is a useful chronological list of shocks felt during the Christian era, down to February 10, 1889; but, except in a few cases, it is little more than a list. Prof. O'Reilly's important catalogues are arranged alphabetically according to the localities affected, and do not pretend to give detailed information with reference to the shocks themselves.

To make our seismic record more complete, I propose, therefore, to compile a descriptive list of British shocks noticed in newspapers and scientific journals from the time at which Mr. Milne's Catalogue closes down to the end of the year 1888; and I should be very grateful if your readers can in any way help me in this work.

What I wish particularly to ask for, however, is information relating to the shocks of the present and future years. For our knowledge of British earthquakes we must at present rely to a great extent on newspaper accounts; and these accounts, which for some points are fairly trustworthy, become difficult of access in after years. If any of your readers are willing to assist me in preserving these notices in a convenient and systematic form, may I ask if they would be good enough to send, to the address below, the names and dates of newspapers, and more especially local ones, in which any descriptions, however short, are given of British shocks? It is hardly necessary to say that any other notes, communicated by those who have felt the shocks or observed their effects, would be of great value, and would be most thankfully received.

The days are past for compiling earthquake catalogues for the

whole surface of the earth, and the value of an attempt at such a task would now be extremely doubtful. But for limited districts, like this country, the case is very different. It would indeed be difficult to over-estimate the value of a seismic record which can claim any approach to completeness for a definite earthquake area, however feeble the shocks which visit it may be.

I may add that I hope shortly to publish some notes or directions for the study of earthquakes, with special reference to those which occur in this country. CHARLES DAVISON.

38 Charlotte Road, Birmingham, October 10.

Effects of Lightning.

I HAVE known of the following case since July last, but owing to absence from this place have only been able to get particulars during the last few days.

During the terrific storm of the 12th of July last, a labourer's cottage was struck by lightning at Leagrave, near here. The lightning descended, according to an eye-witness's report, like a "spout of fire," and struck and descended the chimney, which it destroyed. In the room below there was an old shepherd, an invalid woman, a child, and a shepherd's dog. The shepherd was sitting in a chair leaning on a stick, a kettle was boiling on the fire, and the door was open. The lightning entered the room simultaneously by the chimney and an adjoining window. The window was utterly destroyed, and the kettle was thrown from the fire across the room, the stick on which the shepherd was leaning was torn from his hand and also thrown across the room, the lightning entered a cupboard containing glass and crockery and destroyed every article, and plaster was torn from the walls. The man and woman remained unhurt, but the child was thrown down and its knees stiffened. The dog was struck perfectly stiff, "like a log of wood," and was considered dead. The room seemed full of fire, water, and sulphur, and the occupants said the smell of sulphur was so strong that they would certainly have been suffocated had it not been for the open door. After the storm had abated, the dog, with all its limbs stiff, was laid in a barn, where it very slowly and partially recovered. It long remained both deaf and blind, and was entirely dependent upon smell for its recognition of persons and things. To the present day it has not entirely recovered its injured senses.

Dunstable. W. G. S.

Electrical Cloud Phenomenon.

A SHORT description of a curious cloud appearance observed by me this summer may be of interest to your readers. It was noticed in Kiushu, the southernmost of the three great islands of Japan, early in July, at a distance of ten or twelve miles from the sea.

The season had been, and was, after the time of the observation, an exceptionally rainy one, severe floods being produced in almost all parts of the country, but it was not raining in the place where I made the observation at that particular time. Time shortly after midday, thermometer about 85° F.

The sky was clear overhead, but there was a great bank of heavy "thunderous" looking clouds to the south. It is most difficult to judge even approximately of the distance of clouds, but these might be from one to two miles off; the lower edge was represented by a very nearly straight line, and there was an amount of blue sky visible under the clouds that would perhaps subtend from 10° to 15°.

My attention was attracted to a sort of "tail" of cloud stretching itself downwards from the straight under side of the cloud-bank. It gradually extended till it reached some two-thirds of the distance from the cloud to the earth. It remained of about constant length for a little over ten minutes, the lower end continually waving about in a most curious way, giving the impression almost that it was feeling for something.

Quite suddenly the filament of cloud straightened itself out, and extended itself towards the earth. The lower end became so very thin that, from the distance, it was impossible to see whether it actually made contact with the earth or not, but I have not the smallest doubt that it did, and that a silent discharge took place at the time. There was certainly no sound heard. Immediately after the contact the filament rapidly drew itself up to the cloud, and was incorporated with it. Almost immediately after this, whether as a mere coincidence or not I cannot tell, the cloud discharged a great amount of rain. W. K. BURTON.

Imperial University, Tokio, Japan.

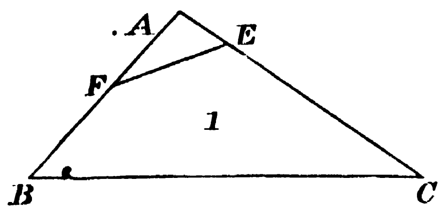
P.S.—The appearance was not unlike the illustrations of "water-spouts" that I have seen, but there was no whirling motion such as is always described as accompanying these, nor, indeed, was there any evidence of violent disturbance of any kind at all.

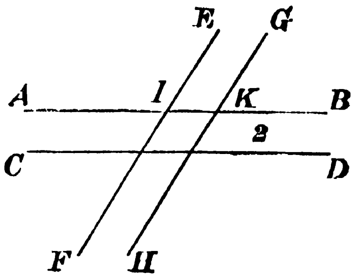
The Use of the Word Antiparallel.

THE following note on the use of the word antiparallel may prove of interest to the readers of NATURE.

In the second edition of "A New Mathematical Dictionary" by E. Stone, F.R.S. (London, 1743), appears a short article on antiparallels, the whole of which I will quote:—

"Antiparallels, are those lines, as FE, BC, that make the same angles AFE, ACB, with the two lines AB, AC, cutting them, but contrary ways, as parallel lines that cut them. But Mr. Leibnitz, in the *Acta Erudit.*, An. 1691, p. 279, calls antiparallels those lines (see Fig. 2) as EF, GH, which cut two parallels AB, CD; so that the outward angle AIF, together with the inward one AKH, is equal to a right angle. When





the sides AB, AC, of a triangle, as ABC (Fig. 1), are cut by a line EF antiparallel to the base BC, the said sides are cut reciprocally proportional by the said line EF; that is, AF : BF :: EC : AE, the triangles AFE, ABC being similar or equiangular."

The error in regard to the ratios of the segments of the sides is the same as the one noted in Hutton's "Miscellanea Mathematica," as quoted by Mr. Langley. I have no doubt that earlier instances of the use of this word can be found, and I would like to know whether the word is used in the first edition of "Stone's Dictionary." W. J. JAMES.

Wesleyan University, Middletown, Conn. U.S.A., October 15.

Fossil Rhizocarps.

IN Bennet and Murray's "Cryptogamic Botany," at p. 115, I am surprised to find in a reference to my paper on "Fossil Rhizocarps" (in *Bull. Ac. Sciences, Chicago*) the statement, with reference to the macrospores of *Protosalvinia*, that "inasmuch as they are borne on Lepidodendron scales this reference is inadmissible." Now no such fact has come to my knowledge, and on the contrary these bodies are found inclosed in cellular sporocarps like those of Salvinia, and are so described in the paper in question. If anyone has found them on "scales of Lepidodendron," the authority should have been stated.

Montreal, October 15. J. WM. DAWSON.

Specific Inductive Capacity.

ON p. 669 of Ganot's "Physics" (eleventh edition) the following statement is found:—"At a fixed distance above a gold-leaf electroscope, let an electrified sphere be placed, by which a certain divergence of the leaves is produced. If now, the charges remaining the same, a disk of sulphur or of shellac be interposed, the divergence increases, showing that inductive action takes place through the sulphur to a greater extent than through a layer of air of the same thickness."

If this statement were correct, there should be less electric action on the side of the ball furthest from the electroscope when the dielectric is interposed. To test this I arranged an experiment as follows:—

The knob of a charged Leyden jar was placed midway between two insulated plates of metal, each plate being in connection with an electroscope. The leaves of each electroscope now diverged to an equal extent.

A plate of ebonite was now placed between the knob of the jar and one of the plates. If the statement above quoted is

correct, the leaves of the electroscope in connection with this plate should show an increased divergence, but the reverse effect was observed. *The leaves partially collapsed.* In all experiments that I have made by inserting dielectrics between a charged body and an electroscope, less electric action has been the result. If while the charged ball be near the electroscope the plate of it be touched with the finger, the leaves collapse, and on removing the finger and then the charged ball they again diverge.

Now let a dielectric be placed between the ball and the electroscope, touch the latter, and remove the finger and ball as before, and much greater divergence will be produced. In both cases the electroscope is charged by induction. Without putting the electroscope to earth, I fail to see theoretically why any greater divergence should occur. I suppose someone must have made the experiment as quoted, but if a greater effect was produced it must have been caused by the substance used for a dielectric being charged itself. I have found very great difficulty in preventing plates of ebonite, paraffin, sulphur, &c., becoming electrified when placed near a charged body.

I should like to know if anyone has experimented in this direction, because either the text-books or myself must be wrong.

In Guthrie's book (p. 101) there is a statement similar to Ganot's. W. A. RUDGE.

Who discovered the Teeth in Ornithorhynchus ?

ON returning from Central Arizona, where I have been engaged in biological explorations, I find upon my desk an important paper entitled "On the Dentition of Ornithorhynchus," by my friend Mr. Oldfield Thomas, Curator of Mammals in the British Museum (see Proc. Royal Soc., vol. xlvi, 1889, 126–131, pl. 2).

The opening sentence of this paper is as follows: "At the meeting of the 9th of February, 1888, Mr. E. B. Poulton communicated to this Society the first discovery of the presence of teeth in *Ornithorhynchus*, a discovery which naturally awakened extreme interest throughout the scientific world." A few lines further on Mr. Thomas continues: "The grand fact of the presence of teeth in Monotremes, and their mammalian nature, are discoveries on which Mr. Poulton may well be congratulated."

From the above I infer that considerable stir has been made by the assumed new "discovery" that the young *Ornithorhynchus* has teeth.

If my British colleagues will turn to the masterly work of their illustrious countryman, Sir Everard Home, they will find in the second volume of his "Lectures on Comparative Anatomy" (published in 1814), no less than three beautifully engraved plates, containing eight figures, of the skull and mouth parts of Ornithorhynchus. Four of these figures show the teeth —two on each side of each jaw. The explanation accompanying Fig. 1, Tab. lix., is as follows: "A view of the upper jaw and palate, to show that there are two grinding teeth on each side." Fig. 2 is "a similar view of the under jaw."

Washington, D.C., October 12. C. HART MERRIAM.

ON THE HARDENING AND TEMPERING OF STEEL.[1]

I.

THE fact that the British Association meets this year at Newcastle no doubt suggested to the Council that it would be well to provide, for the first time since 1848, a lecture on a metallurgical subject. In that year a discourse was delivered at Swansea by Dr. Percy, one of the most learned metallurgists of our time, who has recently passed away, after having almost created an English literature of metallurgy by the publication of his well-known treatises, without which it would have been comparatively barren. It was to him that the country turned in 1851 when it became evident that our metallurgists must receive scientific training.

I know that it has occurred to many that the various problems involved in the "hardening and tempering of steel" must be incapable of adequate treatment in the brief limits of a discourse like this, while others will think that the details of the process, which is practised daily in thousands of workshops, are so well known that it is unnecessary to devote a lecture to the subject. It seemed to me that the entire question was the most important I could choose, partly because it will enable a large number of people who are engaged in industrial work, and who are not expected to think about it in a scientific way, to know how such facts as we shall have to examine have been dealt with by scientific investigators; while those of our members who do not consider that their thoughts or work are scientific in its strictest sense, may perhaps be interested to see how absolutely industrial progress depends upon the advancement of science. This consideration has led me to deal with the subject in a somewhat comprehensive way. The treatment of iron in its several forms is the thing that we as a nation do well. If it be true that national virtues are manifestly expressed in the industrial art of a people, we may recall the sentence in Mr. Ruskin's "Crown of Wild Olive" in which he says, "You have at present in England only one art of any consequence—that is, iron-working," adding, with reference to the manufacture of armour-plate, "Do you think, on those iron plates your courage and endurance are not written for ever, not merely with an iron pen, but on iron parchment?" It may be well, therefore, to consider what properties iron possesses which entitle its application to industrial use to specially represent the skill and patience of the nation.

In 1863, Lord Armstrong, in his address as President of this Association, expressed the hope "that when the time again comes round to receive the British Association in this town, its members will find the interval to have been as fruitful as the corresponding period," since the previous meeting in 1838, "on which they were then looking back." In one way at least this hope has been realized, for the efforts of the last twenty years have resulted in the development of an "age of steel." When the Association last met here, steel was still an expensive material, although Bessemer had, seven years before, communicated his great invention to the world through the British Association at its Cheltenham meeting. The great future in store for Siemens's regenerative furnace, which plays so important a part in the manufacture of steel, was confidently predicted in his Presidential address by Lord Armstrong, than whom no one was better able to judge, for no one had done more to develop the use of steel of all kinds.

Steel, we shall see, is modified iron. The name iron is in fact a comprehensive one, for the mechanical behaviour of the metal is so singularly changed by influences acting from within and without its mass, as to lead many to think, with Paracelsus, that iron and steel must be two distinct metals, their properties being so different. Pure iron may be prepared in a form as pliable and soft as copper, steel can readily be made sufficiently hard to cut glass, and notwithstanding this extraordinary variance in the physical properties of iron and certain kinds of steel, the chemical difference between them is comparatively very small, and would hardly secure attention if it were not for the importance of the results to which it gives rise. We have to consider the nature of the transformations which iron can sustain, and to see how it differs from steel, of which an old writer has said,[1] "Its most useful and advantageous property is that of becoming extremely hard when ignited and plunged into cold water, the hardness produced being greater in proportion as the steel is hotter and the water colder. The colours which appear on the surface of steel slowly heated direct the artist in *tempering* or reducing the hardness of steel to any determinate standard." There is still so much confusion between the words "temper," "tempering," and "hardening," in the writings of even very eminent authorities, that it is well

[1] A Lecture delivered on September 13, by Prof. W. C. Roberts-Austen, F.R.S., before the members of the British Association.

[1] "The First Principles of Chemistry," by W. Nicholson, p. 312 (London, 1790).

to keep these old definitions carefully in mind. I shall employ the word tempering in the sense of softening, as Falstaff uses it when he says of Shallow :—

"I have him already tempering between my finger and my thumb, and shortly will I seal with him." [1]

softening, that is, as brittle wax does by the application of gentle heat. *Hardening*, then, is the result of rapidly cooling a strongly heated mass of steel. *Tempering* consists in re-heating the hardened steel to a temperature far short of that to which it was raised before hardening: this heating may or may not be followed by rapid cooling. *Annealing* consists in heating the mass to a temperature higher than that used for tempering, and allowing it to cool slowly.

First, let the prominent facts be demonstrated experimentally.

[Three sword-blades of identical quality, made by an eminent sword-smith, Mr. Wilkinson, were taken. It was shown by bending one that it was soft; this was heated to redness and plunged into cold water, when it became so hard that it broke on the attempt to bend it. Another was bent into a bow, the arc of which was four inches shorter than the sword itself, a common test for "temper," and it sprang back to a straight line when the bending force was removed; this had been tempered. A third, which had been softened by being cooled slowly, bent easily and remained distorted.]

The metal has been singularly altered in its properties by comparatively simple treatment, and all these changes it must be remembered have been produced in a solid metal to which nothing has been added, and from which nothing material has been taken. The theory of this operation which I have just conducted has been laboriously built up, and its consideration introduces many questions of great interest both in the history of science, and in our knowledge of molecular physics. First as regards the history of the subject. The knowledge that steel might be hardened must have come to us from remote antiquity. Copper hardened with tin was its only predecessor, and it continued to be used very long after it was known that steel might be hardened. It would, moreover, appear that a desire to appreciate the difficulties of a people to whom cutting instruments of hard steel were unknown, seems to have induced experimenters in quite recent times to fashion implements of bronze, and a trustworthy authority tells us that "Sir Francis Chantry formed an alloy containing about 16 parts of copper, 2½ of zinc, and 2½ of tin, of which he had a razor made, and I believe even shaved with it." [2] The Greek alchemical manuscripts which have been so carefully examined by M. Berthelot give various receipts from which it is evident that in the early days the nature of the quenching fluid was considered to be all-important. There were certain rivers the waters of which were supposed to be specially efficacious. Pliny, who says that the difference between waters of various rivers can be recognized by workers in steel, also knew that oil might be used with advantage for hardening certain varieties of the metal. It is sad to think how many of the old receipts for hardening and tempering have been lost. What would we not give, for instance, for the records of the Gallic prototype of our Iron and Steel Institute, the "*Collegium Fabrorum Ferrariorum*," [3] a guild with similar aims, formed in the time of the Roman Republic, for the advancement of knowledge, for the good of the State, and not for that of its individual members? The belief, however, in the efficacy of curious nostrums and solutions for hardening steel could hardly have been firmer at any period than in the sixteenth century of our era. Shakespeare suggests that Othello's sword "of Spain" had been hardened in a cold stream for he says it had

"the ice brook's temper";

but cold water was far too simple a material for many a sixteenth century artificer to employ, as is shown by the quaint recipes contained in one of the earliest books of trade secrets, which, by its title, showed the existence of the belief that the "right use of alchemy" was to bring chemical knowledge to bear upon industry. The earliest edition was published in 1531,[1] and the first English translation [2] in 1583, from which the following extracts may be of interest. "Take snayles, and first drawne water of a red die of which water being taken in the two firste moneths of haruest when it raynes," boil it with the snails, "then heate your iron red hote and quench it therein and it shall be hard as steele." "Ye may do the like with the blood of a man of xxx yeres of age, and of sanguine complexion, being of a merry nature and pleasaunt . . . . distilled in the middst of May." This may seem trivial enough, but the belief in the efficacy of such solutions survived into the present century, for I find in a work published in 1810 that the artist is prettily directed [3] "to take the root of blue lilies, infuse it in wine and quench the steel in it," and the steel will be hard; on the other hand, he is told that if he "takes the juice or water of common beans and quenches iron or steel in it, it will be soft as lead." I am at a loss to explain the confusion which has arisen from this source. As must always be the case when the practice of an art is purely empirical, such procedure was often fantastic, but it is by no means obsolete, for probably at the present day there is hardly a workshop in which some artificer could not be found with a claim to possess a quaint nostrum for hardening steel. Even the use of absurdly compounded baths, to which I have referred, was supported by theoretical views. Otto Tachen,[4] for instance, writing of steel in about the year 1666, says that steel when it is "quenched in water acquires strength because the light alcaly in the water is a true comforter of the light acid in the iron, and cutlers do strengthen it with the alcaly of animals," hence the use of snails. Again, Lemery [5] explains in much the same way the production of steel by heating iron in the presence of horns of animals.

I have dwelt so long on these points in order to bring out clearly the fact that the early workers attached great importance to the nature of the fluid in which hot steel was quenched, and they were right, though their theories may have been wrong. The degree of rapidity with which heat is abstracted from the steel during the operation of hardening is as important at the present day as it ever was. Roughly speaking, if steel has to be made glass-hard, ice-cold water, brine, or mercury, is used; if it has only to be made slightly hard, hot water or oil may be employed; while, as Thomas Gill [6] suggested in 1818, both "hardening" and "tempering" may be united in a single operation by plunging the hot metal in a bath of molten lead or other suitable metal, which will of course abstract the heat more slowly.

We must now trace the development of theories relating to the internal constitution of steel. The advent of the phlogistic school with the teaching of Becher and Stahl led to the view that iron gained phlogiston during its conversion into steel. By phlogiston we know that the early chemists really meant *energy*, but to them phlogiston was represented to be a kind of soul possessed by all metals,

which they could lose by burning and regain by the process they called "revivification." "Hardness [in metals] is caused by the jeiunenese of the spirit and their imparity with the tangible parts," said Francis Bacon;[1] while, according to Stahl,[2] steel was merely iron possessing, in virtue of its phlogiston, the characteristics of a metal in a higher degree; and this view prevails in the writings of Henckel, Newmann, Cramer, Gellert, Rinman, and Macquer. This opinion survived with wonderful persistence, but it did not influence the teaching of Réaumur,[3] who, in 1722, was, so far as I know, the first to suggest a physical theory which has been in any way justified by modern research. He assumed that when steel was heated "sulphurs and salts" were driven out from the molecules, which he represents diagrammatically, into the interstitial space between them. The quenching of the steel and its sudden cooling prevented the sulphurs and salts from returning into the molecules, which were thus firmly cemented by the matter between them, and hard rigid steel was the result. In tempering, the sulphurs and salts partially returned into the molecules, and the metal became proportionately soft. I have elsewhere shown[4] that he used the Torricellian vacuum to demonstrate that the hardening of steel is not accompanied by the evolution of gas, and he concluded that "since the hardening of steel is neither due to the intervention of a new substance nor to the expulsion of air, it only remains to seek its cause in the changes occurring in its structure." Notwithstanding this, the phlogistic school were not daunted, and this brings me to the work of Torbern Bergman, the great Professor at the University of Upsala, who in 1781 showed[5] that steel mainly differs from iron by containing about $\frac{2}{10}$ per cent. of plumbago, while iron does not. Read in connection with modern research, his work seems wonderfully advanced. He was so forcibly impressed by the fact that the great difference in the mechanical properties of different specimens of iron is due to the presence of small quantities of impurity, and that the properties of iron do not vary, as he says, unless by chance the iron has gathered foreign matter, "*nisi forte peregrinum paullo uberius inhærat metallum.*" We find, even, the dawn of the view that under the influence of small quantities of foreign matter iron is, as he calls it, polymorphous, and plays the part of many metals. "*Adeo ut jure dici queat, polymorphum ferrum plurium simul metallorum vices sustinere.*"[6] Unfortunately he confounded the plumbago or carbon he had isolated with phlogiston, as did Rinman in 1782, which was strange, because, in 1774, the latter physicist had shown that a drop of nitric acid simply whitens wrought iron, but leaves a black stain on steel. Bergman tenaciously held to the phlogistic theory in relation to steel; it was inevitable that he should. The true nature of oxidation had been explained; no wonder that the defenders of the phlogistic theory should seek to support their case by appealing to the subtle and obscure changes produced in iron by such apparently slight causes. Bergman's view was, however, combated by Vandermonde, Berthollet, and Monge,[7] who showed in a report communicated to the Académie des Sciences, in 1786, that the difference between the main varieties of iron is determined by variation in the amount of carbon, and further that steel must contain a certain quantity of carbon in order that it might possess definite qualities. Bergman died in 1784, and the report to which I have referred is full of respect for "this grand chemist," as its authors call him, "whom science had lost too soon."

Kirwan's essay on phlogiston,[1] in which Bergman's views were defended, elicited a reply from Lavoisier himself, and brought down the French school in strength to contest almost the last position occupied by the believers in phlogiston.[2]

An entire lecture might be profitably devoted to Bergman's work. His was almost the first calorimetric research, and is specially interesting when taken in connection with the calorimetric investigations of Lavoisier and Laplace in 1780, and it is impossible to read it without feeling that in paying the just tribute to Lavoisier's genius Bergman has been overlooked. He desired to ascertain whether pure iron, steel, and cast iron contain the same amount of heat. He therefore attacked the materials with a solvent, and noted the heat evolved. He says the solvent breaks up the assemblage of the aggregation of molecules and forms other unions. If the new body demands more heat than the body which has been disunited, then the thermometer will fall. If, on the other hand, the degree of heat required is less, the environment will be heated, which will result in the rise of the thermometer. The modern development is that, when a chemical compound is formed, heat is evolved and energy is lost, but if one substance, say a metal, simply dissolves another, the solution is attended with absorption of heat, and the product when attacked by a suitable solvent should evolve practically the same amount of heat, but certainly not less than would be evolved by the individual metals present in solution.[3] This is specially interesting from its relation to the calorimetric work of Lavoisier and Laplace in 1780 and of Lavoisier in 1782, which led the latter to explain the nature of oxidation, and to show that a metal could be as truly "calcined" or oxidized by the action of a solution as by the action of air at an elevated temperature. Now that the importance of thermochemistry is beginning to be recognized in relation to industrial chemistry and metallurgy, it is to be hoped that Bergman's merits will be more fully considered. We are, however, mainly concerned with the fact that he taught us that the difference between iron and steel consists in the $\frac{1}{10}$ to $1\frac{1}{2}$ per cent. of carbon which steel contains. It was only natural that Black, writing in 1796, should have attributed the hardening of steel to the "extrication of latent heat"; "the abatement of the hardness by the temper" being due, he says, "to the restoration of a part of that heat."[4] Black failed to see that the work of Bergman had entirely changed the situation. The next step was made in France. It was considered necessary to establish the fact that carbon is really the element which gives steel its characteristic properties, and with this object in view, Clouet,[5] in 1798, melted a little crucible of iron, weighing 57·8 grammes, containing a diamond, weighing 0·907 gramme, and obtained a fused mass of steel (Fig. 1).

His experiment was repeated by many observers, but the results were open to doubt from the fact that furnace gases could always obtain access to the iron, and might, as well as the diamond, have yielded carbon to the metal.

[2] "Essai sur le Phlogistique," traduit de l'Anglois de M. Kirwan, avec des notes de MM. de Morveau, Lavoisier, de la Place, Monge, Berthollet, et de Fourcroy (Paris, 1788).
[3] See French translation of Bergman's work (Paris, 1783), p. 72. The question is, however, so important that I append the original Latin text:—"Menstruo laxatur compages molecularum, et nova formantur connubia, quæ, si majorem, quam diruta, figunt materiæ caloris quantitatem, in vicinia calor ad restituendum æquilibrium diminuatur oportet, et thermometri hydrargyrum ideo subsidet; si minorem, differentia liberatur et viciniam calefacit, unde etiam adscendit thermometri liquor; si denique nova connubia eamdem præcise quantitatem postulant, quod raro accidit, nulla in thermometro videbitur variatio."—Torberni Bergman, "Opuscula Physica et Chemica," vol. iii. p. 58, 1783 ("De Analysi Ferri").
[4] "Lectures on the Elements of Chemistry," vol. ii p. 505 (1803).
[5] Experiment described by Guyton de Morveau, *Ann. de Chim.*, xxxi. 1799, p. 328.

The carbon might have been presented to the iron in the form of a gas capable of yielding carbon, and this element would as surely have found its way into the steel.

Margueritte,[1] for instance, in 1865, repeated Clouet's experiment, and showed that, although carburization can be effected by simple contact of iron and carbon, it is nevertheless true that in the ordinary process of cementation the gas carbonic oxide plays an important part, which had until then been overlooked. The discovery by Graham,[2] in 1866, of the occlusion of carbonic oxide by

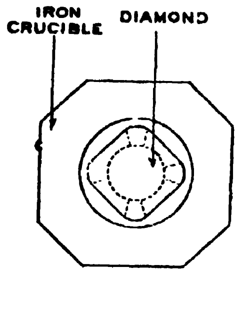

FIG. 1.—Plan of iron crucible and diamond from the drawing in Guyton de Morveau's paper. In the original, the diamond and the crucible are drawn, in plan, separately.

iron, gave additional support to this theory. I am glad to remember that he intrusted the experiments to me.

The question, however, of the direct carburization of iron by the diamond has never been doubted since 1815, when a working cutler, Mr. Pepys,[3] heated iron wire and diamond dust together and obtained steel, the heat being afforded by a powerful electric battery. I am anxious to make this absorption of carbon in the diamond form clear by this diagram (Fig. 2).

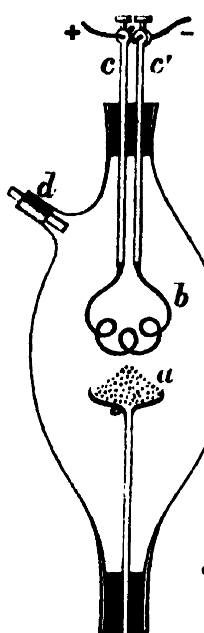

FIG. 2 represents a glass vessel which may either be rendered vacuous or may be filled with an atmosphere of gas through the tube *d*. An iron wire, *b*, placed between the terminals of a battery, *c*, *c'*, is heated to redness, and remains glowing until it is touched by pure diamond dust, which is effected by raising the cup *a*. The iron combines with the diamond dust and fuses.

Do not think for a moment that the steel owes its hardness to the passage of diamond into the iron, *as diamond*. I have repeated Margueritte's form of Clouet's experiment, using, however, a vacuum instead of an atmosphere of gas, and employing the form of apparatus shown in this diagram (Fig. 3). [The carburized iron which was the result of the experiment was thrown upon the screen.] The diamond by union with iron has passed partially at least to the other form of carbon, graphite, while treatment with a solvent which removes the iron shows that carbon has entered into intimate association with the iron, a fact which leads us to the next step in the study of the relations between carbon and iron.

Hempel[1] has shown that, in an atmosphere of nitrogen, iron appears to assimilate the diamond form of carbon more readily than either the graphitic or the amorphous

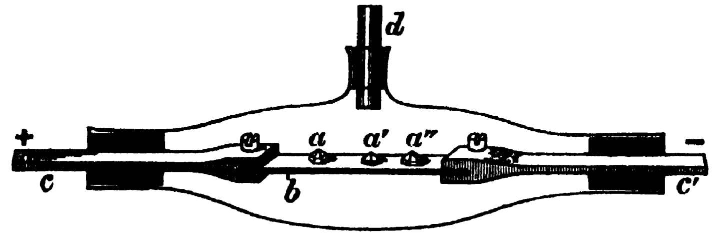

FIG. 3 represents an arrangement for heating the diamond and iron *in vacuo*. A strip of pure iron, *b*, is placed between two terminals, *c*, *c'*, which are connected with a dynamo. The vessel (of glass) is rendered vacuous by connecting the tube *d* with a Sprengel pump. The iron is then heated by the dynamo, and maintained glowing until all occluded gas is expelled from the iron, which is then allowed to cool *in vacuo*. Small pure diamonds, *a*, *a'*, *a''*, are then placed on the strip of iron through the orifice into which the tube *d* fits. The vessel is rendered vacuous, and when the iron is again heated in contact with the diamonds it fuses and combines with them.

forms, but directly carbon is associated with *molten* iron it behaves like the protean element it is, and the state which this carbon assumes is influenced by the rate of cooling of the molten mass, or even by the thermal treatment to which the solidified mass is subjected. Let me repeat, all are familiar with carbon in the distinct forms of diamond, graphite, and soot: all are alike carbon. It need not be considered strange, then, that carbon should be capable of being present in intimate association with iron, but in very varied forms.

Now the mode of existence of carbon in soft annealed steel is very different from that in which it occurs in hard steel. I believe that Karsten was the first to isolate, in 1827, from soft steel a true compound of iron and carbon. Berthier[2] also separated from soft steel a carbide of iron, to which he assigned the formula FeC; but to attempt to trace the history of the work in this direction would demand an entire lecture. I will only add that within the last few years Sir F. Abel has given much experimental evidence in favour of the existence in soft cold rolled steel of a carbide, Fe_3C, which he isolated by the slow solvent action of a chromic acid solution. His work has been generally accepted as conclusive, and has been the starting-point of much that has followed.

It will occur to you that the microscope should reveal wide differences between the structure of various kinds of iron and steel, and I am happy to be able to give you enlarged diagrams made from the drawings of Mr. Sorby, the eminent microscopist, which illustrated his very delicate investigations into the structure of steel.[3]

The point I am mainly concerned with is the existence of a substance which Sorby called the "pearly constituent" in soft steel. This pearly constituent is closely related to the carbide of iron, Fe_3C of Abel,[4] and is probably a mixture of Fe_3C and pure iron. I have diagrammatically indicated its presence in Fig. 4, which will enable me to summarize the work of many experimenters. The diagram (Fig. 4) will serve, for the purpose of illustration,

to indicate the appearance when soft, hardened, and tempered steel are respectively treated with a solvent which acts gently on the mass.

IRON AND CARBON.

(0·2 TO 1·5 PER CENT OF CARBON.)

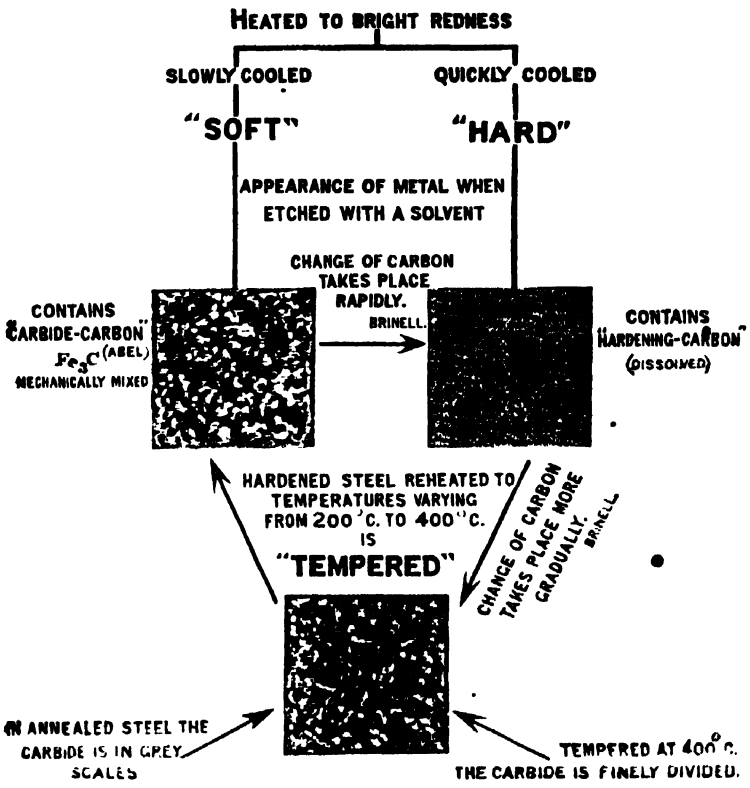

FIG. 4.

A study of the above diagram and of the admirable work of Ledebur[1] will show how complex the relations of carbon and iron really are, but, for the purposes of the present inquiry it may fairly be asked, Does a change in the "mode of existence" of carbon in iron sufficiently explain the main facts of hardening and tempering? It does not. It is possible to obtain by rapid cooling from a certain temperature steel which is perfectly soft, although analysis proves that the carbon is present in the form which we have recognized as "hardening carbon." No doubt in the hardening of steel the carbon changes its mode of existence, but we must seek some other theory to explain all the facts, and in order to do this we will turn to the behaviour of the iron itself.

In approaching this portion of the subject a few elementary facts relative to the constitution of matter must be recalled, and in doing so I must again appeal briefly to history. It is universally accepted that metals, like all elements, are composed of atoms of definite weights and volumes grouped in molecules. In order actually to transmute one metal into another it would be necessary to discover a method of attacking not the molecule but the *atom*, and of changing it, and this, so far as is known, has not yet been done; but it is possible, by influences which often appear to be very slight, to change the relations of the molecules to each other, and to alter the arrangements or distribution of the *atoms* within the *molecules*, and by varying in this sense the molecular arrangement of certain elements, they may be made to pass into forms which are very different from those in which we ordinarily know them. Carbon, for instance, when free, or when associated with iron, may readily be changed from the diamond to the graphitic form, though the converse change has not as yet been effected.

Sulphur, again, with which you are familiar as a hard, brittle, yellow solid, may be prepared and maintained for a little time in the form of this brown viscous mass, but this latter form of sulphur soon passes spontaneously and slowly at the ordinary temperature, and instantaneously at 100°, to the solid octahedral yellow modification with evolution of heat. The viscous form of sulphur is an allotropic modification of that element. A few cases of allotropy in metals have already been established, and when they do occur they give rise to problems of vast industrial importance. Such molecular changes in metals are usually produced by the addition of a small quantity of foreign matter, and I have elsewhere tried to show that the molecular change produced by the action of *traces* upon *masses* is a wide-spread principle of nature, and one which was recognized at the dawn of the science of chemistry, even in the seventh century, although distorted explanations were given of well-known facts, and gave rise to entirely false hopes. But it is the same story now as in mediæval times: the single grain of powder which Raymond Lully said would transmute millions of its weight of lead into gold—the single grain of stone that Solomon Trismosin thought would secure perpetual youth—had their analogues in the small amount of plumbago which, to Bergman's astonishment in the eighteenth century, converted iron into steel. By his time it was recognized that the right use of alchemy consisted in the application of its methods to industry, and we still wonder at the minuteness of the quantity of certain elements which can profoundly affect the properties of metals. The statements are true, and are not derived from poetical literature, early or late. Even in the moral world the significance of the action of traces upon masses has been recognized, and the method of the alchemist survives in the administration of the small quantity of powder which, in the imagination of Robert Louis Stevenson, will produce the malevolent Hyde modification of the benevolent Dr. Jekyll. In thus borrowing an illustration from one of the most refined and subtle writers of our time, I do not fear the taunt of Francis Bacon,[1] that "sottishly do the chymics appropriate the fancies and delights of poets in the transformation of bodies to the experiments of their furnaces;" for, although it may not be possible to *transmute* metals, it is easy so to *transform* them, by very slight influences, that as regards special service required from them they may behave either usefully or entirely prejudicially.

In attempting to illustrate this part of the subject I cannot take the most striking cases, as it is difficult to demonstrate them in the time at my disposal. The following experiment, which does not, however, depend upon the action of a trace upon a mass, will enable me to lead up to the point I wish to insist upon. It consists in the release of gold from its alloy with potassium. When the alloy is treated with water, the gold comes down in a finely divided, dark brown, chemically active state. [Experiment shown on the screen.]

I have chosen this experiment because it was a similar one that first roused suspicion that pure iron could exist in more than one form.

The question at once suggests itself, Can iron behave in a similar manner: is an allotropic form of iron known? Joule afforded experimental evidence for an affirmative answer to this question nearly forty years ago by communicating to the British Association in 1850 a paper on some amalgams. The result of his experiments, published in detail later,[2] in a paper which has been sadly neglected, showed that iron released from its amalgam with mercury is chemically active, as it com-

[1] *Stahl und Eisen*, vol. viii., 1883, p. 742.

[1] Preface to the "Wisdom of the Ancients."

[2] "On some Amalgams," Mem. Lit. Phil. Soc. Manchester, vol. ii. [3] p. 115.

bines readily with the oxygen of the air at the ordinary temperature, and he claims that the iron so set free is allotropic; but Joule did much more than this. Magnus had shown (1851) that the thermo-electric properties of hard and soft steel and iron differ. Joule, in a paper on some thermo-electric properties of solids, incidentally shows that the generation of a thermo-electric current affords a method of ascertaining the degree of carburization of iron, and he appeals to the "thermo-electricity of iron in different states" as presenting a "fresh illustration of the extraordinary physical changes produced in iron by its conversion into steel," and he adds the expression of the belief "that the excellence of the latter metal might be tested by ascertaining the amount of change in thermo-electric condition which can be produced by the process of hardening."[1] It is by a thermo-electric method that the views as to the existence of iron in allotropic forms has been confirmed. Jullien seems to have inclined to the view that iron is allotropic in his "Théorie de la Trempe,"[2] published in 1865, but he cannot be said to have added much to our knowledge, although he certainly directed attention to the importance of hardening and tempering steel.

The next step was made in Russia, in 1868. Chernoff, who has found an admirable exponent to English readers in Mr. W. Anderson, President of Section G, showed that steel could not be hardened by rapid cooling until it had been heated to a definite temperature—to a degree of redness which he called *a*. Then in 1873, Prof. Tait[3] used this expression in a Rede Lecture delivered at Cambridge: "It seems as if iron becomes, as it were, a different metal on being raised above a certain temperature; this may possibly have some connection with the ferricum and ferrosum of the chemists." He also published his now well-known "first approximation to a thermo-electric diagram," which is of great interest in view of recent work. At about this time those specially interested in this question remembered that Gore[4] had shown that a curious molecular change could be produced by heating an iron wire, which sustains a momentary elongation on cooling. Barrett repeated Gore's experiment, and discovered that as an iron wire cools down it suddenly *glows*, a phenomenon to which he gave the name *recalescence*, and these investigations have been pursued and developed in other directions by many skilful experimenters.[5] In 1879, Wrightson[6] called attention to the abnormal expansion of carburized iron at high temperatures.

The next point of special importance seems to me to be that recorded by Barus, who, by a thermo-electric method, showed, in an elaborate paper published in 1879,[7] that "the hardness of steel does not increase continuously with its temperature at the moment of sudden cooling, but at a point lying in the dark-red heat the glass-hard state" may suddenly be attained by rapid cooling. I shall have again to refer to the remarkable series of papers published by Barus and Strouhal,[8] embodying the results of laborious investigations, to which, in the limited space of this lecture, I can do but scanty justice; and finally, within the last few years, Pionchon[1] showed that at a temperature of 700° the specific heat of iron is altogether exceptional, and Le Chatelier[2] has detected that at the same temperature a change occurs in the curve representing the electromotive force of iron—both experimenters concluding that they had obtained evidence of the passage of iron into an allotropic state.

Osmond,[3] in France, then made the observations of Gore and Barrett the starting-point of a fresh inquiry, which will now be considered at some length, as Osmond has arrived at conclusions of much interest and importance.

[3] The reader will find the principal part of Osmond's work in the following papers: Osmond et Werth, "Théorie Cellulaire des Propriétés de l'Acier," *Ann. des Mines*, viii., 1885, p. 5; "Transformations du Fer et du Carbone," Paris, Baudoin et Cie., 1888; "Études Métallurgiques," *Ann. des Mines*, Juillet-Août, 1888. There is also a very interesting paper, "Sur les Nouveaux Procédés de Trempe," which he communicated to the Mining and Metallurgical Congress, Paris, 1889.

ON A NEW APPLICATION OF PHOTOGRAPHY TO THE DEMONSTRATION OF CERTAIN PHYSIOLOGICAL PROCESSES IN PLANTS.

MR. WALTER GARDINER, Lecturer on Botany in the University of Cambridge, who delivered the evening address at Newcastle on "How Plants maintain themselves in the Struggle for Existence," has discovered a new method of printing photographic negatives, employing living leaves in place of sensitive paper. Mr. Gardiner read a paper on the subject before the British Association. Before dealing with the immediate subject of his paper, the author described how prints may be obtained from *Protococci*, or the free-swimming swarm-spores of many green Algæ. It is possible to take advantage of their sensitiveness to light. Into one end of a water-tight box, a thin glass plate is securely fitted. The negative to be printed is then placed next the glass, film side nearest. The box is filled with water containing a fairly large quantity of swarm-spores. The lid is shut down, and the whole is exposed to diffused light. In the case of a strong and well-developed negative, the swarm-spores swim towards the most highly-illuminated parts, and there in the greatest numbers come to rest, and settle upon the glass, so that, after some four or six hours, on pouring out the water and removing the negative, a print in green swarm-spores can be obtained. The print may be dried, fixed with albumen, stained, and varnished. The author then dwelt upon the well-known fact that the whole of the animal life upon the globe depends directly or indirectly upon the wonderful synthetic formation of proteid and protoplasm which takes place in the living tissue of plants containing chlorophyll, *i.e.* green plants, or, to be more exact, in the green chlorophyll corpuscles. He stated that, whatever is the exact chemical nature of the process, this is at least clear, that the first *visible* product of the assimilatory activity is starch, which, moreover, is found in the chlorophyll grains. The presence of this starch can be made manifest by treating a decolorized leaf with a water solution of iodine dissolved in potassic iodide. This formation of starch only takes place under the influence of light; the radiant energy of the sun providing the means of executing the profound synthetic chemical change, and building up proteid from the carbonic acid of the air which is taken up by the leaves and the salts and water of the soil absorbed by the roots. If a plant (and preferably a plant with thin leaves) be placed in the dark over-night, and then brought out into the light next morning, the desired leaves being covered with a sharp and well-developed negative, starch is formed

when light is transmitted, and in greatest quantity in the brightest areas. Thus a positive in starch is produced which can be developed by suitable treatment with iodine. [A leaf was then developed, and handed round to the audience for inspection.] The author showed that it might be possible to obtain a permanent print by suitable washing and treatment with a soluble silver salt, silver iodide being formed. The author regards this discovery as a most striking illustration of the way in which plants are working for themselves, and so for all living things, and points out that the extraordinary manner in which the green parts of plants (so to speak) catch the radiant energy of the sun, and employ it for analytical and synthetical chemical processes, may be easily and clearly demonstrated.

NOTES.

WE understand that the late Mr. John Ball, F.R.S., has bequeathed his botanical library and herbarium to Sir Joseph Hooker, to the Director of the Royal Botanic Gardens at Kew for the time being, and to the President of the Royal Society for the time being, requesting them to give the same to such person or persons or public institution in this country, the British colonies, or elsewhere in the world, as they or any two of them may select, with the sole object of promoting the knowledge of natural science. Right is, however, reserved for Kew to select previously such specimens or books as it may want.

THE following is the list of names recommended by the President and Council of the Royal Society for election into the Council for the year 1890, at the forthcoming anniversary meeting on the 30th inst.:—President: Sir George Gabriel Stokes, Bart. Treasurer: Dr. John Evans. Secretaries: Prof. Michael Foster, the Lord Rayleigh. Foreign Secretary: Dr. Archibald Geikie. Other Members of the Council: Prof. Henry Edward Armstrong, Prof. William Edward Ayrton, Charles Baron Clarke, Prof. W. Boyd Dawkins, Dr. Edward Emanuel Klein, Prof. E. Ray Lankester, Dr. Hugo Müller, Prof. Alfred Newton, Captain Andrew Noble, C.B., Rev. Stephen Joseph Perry, Sir Henry E. Roscoe, Dr. Edward John Routh, William Scovell Savory, Prof. Joseph John Thomson, Prof. Alexander William Williamson, Colonel Sir Charles William Wilson, R.E.

IN the list of Englishmen decorated in connection with the British Section of the Paris Exhibition, the names of the following men of science are included:—Grand Officer of the Legion of Honour: Sir William Thomson, F.R.S. Officers of the Legion of Honour: Sir Douglas Galton, K.C.B., Sir Henry Roscoe, M.P., F.R.S., Mr. W. H. Preece, F.R.S. Chevaliers of the Legion of Honour: Prof. Francis Elgar, Prof. W. Roberts-Austen, F.R.S., Dr. C. Le Neve Foster. Officer of Public Instruction: Mr. C. V. Boys, F.R.S.

THE Naturforschende Gesellschaft at Emden is to celebrate its seventy-fifth anniversary on December 29 next. The Society was founded in 1814 by twenty-four burgesses of Emden. The festivities in December will consist of a general meeting of the Society and the Society's correspondents at noon in the Museum, and a *Festessen* at four o'clock.

A REPORT of the proceedings of the International Zoological Congress, held in Paris two months ago, will be published shortly.

A FRENCH translation of Dr. Wallace's "Darwinism" will be published next year.

THE greater part of the ethnographical collection sent to the Paris Exhibition is to remain in Paris, in the Colonial Museum.

THE following botanical appointments are announced:—The Directorship of the Botanic Garden at Berlin, vacant by the death of Dr. Eichler, having been conferred on Prof. Engler, of Breslau, Prof. Urban becomes Second Director of the Berlin Botanic Garden; and Prof. Prantl, of Aschaffenburg, succeeds Prof. Engler as Director of the Botanic Garden at Breslau. Prof. Sadebeck, of Hamburg, is appointed Director of the Botanic Garden in that town, in the place of the late Dr. Reichenbach. Dr. G. von Lagerheim vacates the Professorship at Lisbon, to which he was lately appointed, and goes to Ecuador as Professor of Botany and Director of the Botanic Garden at Quito. Dr. H. Molisch, of Vienna, takes the Chair of the late Dr. Leitgeb in the Polytechnic at Gratz. Dr. F. Hueppe is appointed Professor of Bacteriology at the University of Prague, and is succeeded in the same Chair at Wiesbaden by Dr. G. Frank, of Berlin. The venerable Professor von Naegeli retires from the Directorship of the Botanic Garden at Munich. Mr. F. S. Earle, Prof. E. S. Goff, and Prof. L. R. Taft have been appointed special agents in the Section of Vegetable Pathology of the United States Department of Agriculture. Mr. H. H. Rusby has been appointed Professor of Botany and Materia Medica in the New York College of Pharmacy.

THE Economic Museum, Calcutta, has completed and despatched the first instalment of important Indian fibres required by the India Office for presentation to the Museums of the Royal Botanical Gardens at Kew and Edinburgh, and to the Chambers of Commerce at Dundee and Manchester.

A PRIZE of about £20 is offered by the Geographical Societies of Dresden and Leipzig, for "a physico-geographical description of the course of the Elbe between Bodenbach and its entrance on the flat country, with special reference to depth, quantity of water and its variations, ice, and changes in the form of the banks." The date is the end of 1890.

IN his address at the opening of the winter session of the University of Toronto, Sir Daniel Wilson, the President of the University, referred to the recent Toronto meeting of the American Association for the Advancement of Science. "Everything available for the special requirements of the Association," he said, "was placed at the disposal of the Sections; and we are gratified by the assurance that, at the close of a highly successful meeting, our visitors carried away with them pleasant memories of their reception here." The meeting of the representatives of science in the buildings of the Toronto University was in some respects, as the President pointed out, peculiarly opportune. "The long-felt need of adequately furnished and equipped laboratories and lecture-rooms for our scientific staff was anew brought into prominence by the restoration to the University of its Medical Faculty; and we now enter on the work of another year provided with buildings admirably adapted for biological and physiological study and research. Plans, moreover, have been approved of, which, when carried out to their full extent, will furnish equally satisfactory accommodation for the departments of botany, chemistry, geology, and palæontology, along with laboratories, work-rooms, museum, and other requisites for efficient instruction in the various branches of science."

THE thirty-fourth general meeting of the Society for Psychical Research was held on Friday afternoon, October 25, at the Westminster Town Hall. The President (Prof. Sidgwick) gave an account of the International Congress of Experimental Psychology held in Paris last August. The Congress had adopted the scheme of a census of hallucinations, already set on foot by the Society for Psychical Research in England, France, and the United States, and it was hoped that the collection of statistics might gradually be extended to other European countries. Much matter valuable to psychologists was

thus being collected; and he trusted that fresh light would be thrown on the subject of coincidental or veridical hallucinations, which specially interested their Society. He would be glad to supply information in reply to letters addressed to him at Hill Side, Cambridge. A paper on recent telepathic experiences was also read.

WE learn from *Humboldt* that the project of a lacustrine biological station on Lake Plön, in East Holstein, is likely to be soon carried out, thanks to the energy of Dr. Otto Zacharias, and the liberality of the Bohemian Baron Bela Dertcheni. This station is to afford Prof. Anton Fritsch, of Prague, and his assistants, constant opportunities of research on fresh-water fauna. The scheme finds a good deal of favour in Berlin, and it is hoped that the researches at the station may prove of considerable benefit to fisheries.

WE send to America some return for the Colorado beetle and the Canadian water-weed. The "weed-law" of the State of Wisconsin requires from farmers, under penalties, the destruction of the following weeds:—*Cnicus arvensis*, *Arctium Lappa*, *Chrysanthemum Leucanthemum*, *Sonchus arvensis*, *Xanthium strumarium*, *Linaria vulgaris*, and *Rumex crispus*. Only one of these is a native of the United States; all the rest being naturalized importations from Europe, and common wild plants in this country.

PROF. RIGHI showed, last year, that ultra-violet radiations reduce to the same potential two conductors, a plate and a piece of netting, applied to each other, the rays being thrown on the netting-side. He now points out (*Riv. Sci. Ind.*, July–August) that this suggests a very simple and convenient way of measuring differences of potential of contact. One notes the deflection of an electrometer connected with the plate (the netting being permanently connected with earth); then, having connected the electrometer for an instant with earth, makes the radiations act a sufficient time. He used a zinc electric lamp, and the metals examined were placed in some cases in a bell jar, to which some gas or vapour was admitted. From measurements of different plates with the same metallic net (copper, zinc, or platinum), the differences of potential of pairs of metals could be deduced. Prof. Righi found the differences sensibly the same in dry and moist air and in carbonic anhydride; but with hydrogen, very different values (from those in air) appeared, where one of the metals examined was platinum, palladium, nickel, or iron (doubtless owing to absorption). In ammonia all the metals examined with zinc net, seemed to have become less oxidizable; and in coal gas, carbon and platinum behaved like more oxidizable metals. A memoir on the subject will shortly appear.

IN an interesting paper on the management of aquaria, printed in the Bulletin of the United States Fish Commission, Mr. W. P. Seal points out that, in the feeding of the fish, care must be taken to introduce no more food than they can eat in a short time, as what is not eaten will soon decompose and make the water cloudy, and generate noxious gases as well. If due care is observed in regard to quantity, it does not matter how often fish are fed, except that if fed abundantly they will grow rapidly, which is not generally desired. Fish may be fed every day, or but two or three times a week, with equally good results apparently. They will always find a small amount of food in the aquarium in the vegetation. Where they are not fed sufficiently, they are apt to strip the plants of their leaves. In a natural condition fish are feeding continually and grow very rapidly.

ON November 2 a slight shock of earthquake was felt in St. Louis, U.S.A., and the vicinity.

THE following summary of the phases of Vesuvius during the past year has been supplied by Prof. Palmieri, of the Vesuvian Observatory of the University of Naples, to the British Consul there, and is appended by the latter to his last Report. Mount Vesuvius, during the past year, has continued its moderately eruptive activity, which began in the month of December 1875. There were various emissions of small lava streams, which did not reach further than the base of the cone. An additional cone was gradually formed, caused by the activity of the motive power of the crater which, towards the end of the year, had reached a height of 100 metres (equal to 328 feet) above its original level. On various occasions the detonations and the red-hot projectiles thrown up with the large quantities of smoke indicated greater eruptive power. During the whole year no ashes were thrown up, and consequently the crops in the surrounding country were not destroyed. The sublimations on the smoke issues were relatively scarce, and did not present any product that called for attention. The seismographic instruments at the Observatory did not show an activity proportionate to that of the volcano. All the lava streams that issued during the year flowed towards the eastern slopes of the mountain.

THE Meteorological Council have published Part I. of the Quarterly Weather Report for 1880. The work is (as before) divided into three sections: (1) a general summary of the chief features of the weather for the quarter; (2) tables showing the movements and peculiarities of the principal cyclonic and anticyclonic systems; and (3) remarks on the distribution of the various elements for each month, illustrated by charts. An appendix contains tables and diagrams illustrating the diurnal range of the barometer in Great Britain and Ireland during the years 1876–80, by F. C. Bayard. The data used are the hourly observations at seven Observatories in connection with the Meteorological Office, and at Greenwich and Liverpool Observatories. The paper shows that, even in these high latitudes, the daily range is well marked during all months, notwithstanding the interference caused by non-periodic changes. Important seasonal differences are shown, the morning maximum being distinctly higher than the evening maximum in winter, while in summer the evening maximum is the higher of the two. The values exhibit the influence of locality on the amplitude and epoch of the diurnal inequalities, and furnish material for more minute inquiry.

IT is interesting to read of a part of the world where the buffalo is not dying out, but increasing in numbers. A journal of Perth, in Western Australia, says that few Australians are aware that certain parts of Northern Australia have vast herds of the wild buffalo (*Bos bubalus*) careering over its plains and wallowing in its shady pools. The *Sydney Mail* states that the animals are massive and heavy, with splendid horns, and afford sport of a sufficiently dangerous nature to possess charms for the most daring hunter, a wounded buffalo being one of the most dangerous animals known, his great weight, prominent horns, and splendid courage, making him as well respected as sought after. The first buffaloes were landed at Port Essington, North Australia, about the year 1829.

THE *Naturalist's Gazette* has issued an excellent series of what it calls "label lists." On one sheet there is a list of British birds' eggs; on another, a list of dragon-flies; on another, a list of British butterflies; and so on. The names are printed in suitable type on gummed paper, and collectors, in labelling their specimens, will find the lists of considerable service.

THE next volume of Messrs. Ward, Lock, and Co.'s "Minerva Library of Famous Books" will be "Travels on the Amazon and Rio Negro," by Dr. Alfred Russel Wallace.

F. A. BROCKHAUS, 16 Querstrasse, Leipzig, has issued a catalogue, in four parts, containing lists of works relating to various branches of botany.

THE *Colonies and India* states that a discovery has recently been made on a Fiji plantation, which will probably prove extremely valuable in all tropical countries where the cultivation of bananas is regarded as a settled industry. The banana disease had for some time been causing much havoc on a plantation on Vanua Levu, and it appears that the discovery of an antidote was due to an accidental occurrence. On a flat near the sea-shore there was a patch of bananas much diseased, and some time ago the sea swept into it and remained on it for about an hour. All the plants were killed as far as the standing stems were concerned, but vigorous young shoots came up freely from the roots, and were not only quite free from disease, but soon began to bear much larger bunches of fruit than the parent plants ever did. Upon noting this effect the planters determined to try the experiment upon a number of badly diseased plants which the sea had not reached. They cut down the diseased plants, and, having stirred the ground about them, poured from one to four buckets of sea-water over each. The result was that, while the parent stems withered, vigorous young shoots came freely away, without a sign of disease.

A SERIES of successful experiments upon the simultaneous production of pure crystals of sodium carbonate and chlorine gas from common salt are described by Dr. Hempel in the current number of the *Berichte*. The experiments simply consisted in passing a current of carbon dioxide gas through a solution of salt contained in a special form of electrolytic cell, through which an electric current from a few Bunsen's cells or a small dynamo was circulated. The kathode found most convenient consisted of a plate of iron or carbon perforated with numerous holes about 4 millimetres in diameter, bored obliquely, so that bubbles of gas could readily escape upwards. For anode a similar plate of thin perforated carbon was employed. Both electrodes were circular in shape, and between them was placed a diaphragm of thick asbestos paper, which was directly squeezed between the two plates. This arrangement was found to possess the double advantage of bringing the two electrodes within 1 millimetre of each other, and so greatly diminishing the internal resistance, and of affording such excellent support to the asbestos diaphragm that any rupture of the latter was entirely prevented. The electrodes and their enclosed diaphragm were supported in a circular glass cell in such a manner that they divided the cell into two distinct chambers. To the glass wall of the cell on the positive or anode side was fitted a wide side tube, through which the salt was supplied as often as necessary in solid pieces, a little water being also from time to time added to replace that taken up in the crystallization of the sodium carbonate. A delivery tube was also attached to the upper portion of the anode chamber in order to conduct away the liberated chlorine gas. The negative or kathode chamber was supplied at its upper end with an opening serving on the one hand to introduce the carbon dioxide delivery tube, and on the other to extract the crystals of sodium carbonate. The apparatus was thus found to work continuously for weeks together, the asbestos diaphragm withstanding the pressure very satisfactorily. The separation of the soda crystals is readily explained by the well-known fact of the difficult solubility of sodium carbonate in solutions of sodium chloride; as fast as the electric current decomposes the sodium chloride into chlorine and sodium, the carbon dioxide converts the sodium hydrate formed by the reaction of the sodium upon water into the normal carbonate, which, in presence of the constantly-replenished common salt, at once separates in the usual monoclinic form of $Na_2CO_3 . 10H_2O$. The total resistance of the cell is only about five and a half volts, which may be still further reduced by constructing both electrodes of carbon. Using a small dynamo-electric machine, 64·5 grams of chlorine and 259·8 grams of $Na_2CO_3 . 10H_2O$ per horse-power of 680 volt-amperes were produced per hour, so that the experiments, in addition to their interest from a purely chemical point of view, may turn out to bear fruit technically. The soda produced is stated to be chemically pure, and the chlorine to contain but a very small admixture with other gases.

THE additions to the Zoological Society's Gardens during the past week include a Patas Monkey (*Cercopithecus patas* ♂) from West Africa, presented by the Rev. James Vernall; a Cheetah (*Cynælurus jubatus* ♂) from South Africa, presented by Captain M. P. Webster, s.s. *Roslin Castle*; a Ring-tailed Coati (*Nasua rufa* ♀) from South America, presented by Mr. J. A. Martin; two Short-toed Larks (*Calandrella brachydactyla*) from Devonshire, presented by Commander W. N. Latham, R.N., F.Z.S.; a Sharp-nosed Crocodile (*Crocodilus acutus*) from Jamaica, presented by the Jamaica Institute; two Tuatera Lizards (*Sphenodon punctatus*) from New Zealand, presented by Rear-Admiral Henry Fairfax, R.N., C.B., F.Z.S.; a Smooth-headed Capuchin (*Cebus monachus* ♂) from Brazil, deposited; a Collared Peccary (*Dicotyles tajaçu* ♀), four Rosy-billed Ducks (*Metopiana peposaca* ♂ ♂ ♀ ♀) from South America; two Grey Squirrels (*Sciurus cinereus*) from North America; four Finches (*Munia nana*) from Madagascar, purchased.

OUR ASTRONOMICAL COLUMN.

STELLAR PARALLAX BY MEANS OF PHOTOGRAPHY.—Prof. Pritchard has sent us his eminently successful "Researches in Stellar Parallax" by the aid of photography, from observations made at the Oxford University Observatory. The advantage in point of convenience and rapidity in the multiplication of observations which this method possesses over all others is incalculable, and it is interesting to note that in the case of 61_1 Cygni the parallax obtained was 0''·4294 ± 0''·0162, and that Bessel's probable error is practically identical with this here stated. Hence, as far as the present results are concerned, photographic and heliometric measures of parallax may be regarded as possessing an equality of accuracy.

The following list contains the stars whose parallax has been determined by this novel method, and some of the results obtained:—

61_1 Cygni	+ 0''·429	± 0''·016
61_2 ,, ...	+ 0·432	± 0·019
μ Cassiopeiæ	+ 0·021	± 0·023
Polaris	+ 0·052	± 0·011
α Cassiopeiæ	+ 0·035	± 0·024
β ,, ...	+ 0·157	± 0·036
γ ,, ...	− 0·032	± 0·026
α Cephei	+ 0·073	± 0·031

The almost identical parallax of the two components of 61 Cygni is worthy of note. The average of eight determinations gives a value 0''·437, which is a close approximation to Dr. Belopolsky's value of 0·50 as the *absolute* parallax of 61 Cygni.

Bessel determined a small negative parallax for μ Cassiopeiæ, but Dr. Struve assigned it a value + 0''·342. The very small positive parallax given by Prof. Pritchard may be explanatory of Bessel's negative determination.

The small negative parallax found for γ Cassiopeiæ would indicate that it and the comparison stars are in the same group, although its bright line spectrum points to a constitution different from that of other stars in this constellation.

Even a cursory examination of the summary of results renders it evident that no relation exists between the lustre and parallax of stars, and indeed, since we probably view bodies which are still in various stages of condensation, we should hardly expect to find any such relation.

MEASUREMENTS OF DOUBLE STARS.—*Astronomische Nachrichten*, Nos. 2929–30, contain a series of double star observations made with the 36-inch refractor of the Lick Observatory by Mr. S. W. Burnham. The discovery is claimed of two very faint stars in the trapezium of Orion, and an excessively faint double has also been detected by Mr. E. E. Barnard just outside and preceding the trapezium. The observers believe that, in spite of the numerous alleged discoveries of faint stars in this

region, it is impossible to see such as these now found with an aperture much less than that of the Lick telescope. A list is therefore given of the principal communications to astronomical periodicals relating to the alleged discovery of faint stars in the trapezium of Orion.

BARNARD'S COMET, 1888–89.—*Comptes rendus*, No. 17, October 21, 1889, contains some observations made by MM. Rayet and Courty of the motion of Barnard's comet, the positions of the comparison stars being also given. The series of observations extend from September 11, 1888, to September 27, 1889.

BIOGRAPHICAL NOTE ON J. C. HOUZEAU.—M. A. Lancaster, the collaborator with Houzeau of the most comprehensive bibliography extant, has proved himself, in this note, to be the most capable of writing his deceased friend's biography. Houzeau's scientific and literary labours cover an extensive field: astronomy and geodesy, mathematics and meteorology, geology and geography, are all represented in his works; and when but a young man, he directed the triangulation of his country. In politics Houzeau was an enthusiast, and whilst in America, about 1861–69, he gave a considerable amount of attention to the subject of the emancipation of the slaves, and wrote numerous and important articles upon it. In 1875, Houzeau completed a series of astronomical and meteorological observations made at Jamaica, and in the following year was appointed Director of the Brussels Observatory. His crowning work—the "Vade Mecum of Astronomy," was finished in 1882. It represented the work of a lifetime, and as a guide to astronomers is invaluable. Such a compilation, however, calls for continual additions, and a general bibliography was published in 1887, with the assistance of M. A. Lancaster. This was Houzeau's last work, but before his death, on July 12, 1888, he earnestly expressed the wish that it should be carried on by his collaborator. Houzeau's life was full of vicissitudes, and his biography is most interesting.

THE KARLSRUHE OBSERVATORY.—The third volume of the Publications of the Grand-Ducal Observatory of Karlsruhe has recently been published by Dr. W. Valentiner, the Director. The bulk of the volume is by Dr. E. von Rebeur-Paschwitz, and consists, first, of a series of measures with the 6-inch refractor of the two star-clusters M. 35 and M. 25; secondly, of a discussion of the orbit of Comet Wells, 1882 I., and the derivation of definitive elements; and lastly, of auxiliary tables for the computation of parallax for 169 different observatories.

Dr. Boy Mattheissen adds a short paper on the orbit of Comet Denning, 1881 V.

The volume contains three plates, the first two being maps of the star-clusters under observation, whilst the third gives photographs of the same two clusters as taken by Dr. E. von Gothard at Herény.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich, at 10 p.m. November 7 = 1h. 9m. 9s.

Name.	Mag.	Colour.	R.A. 1890·0.	Decl. 1890·0.
			h. m. s.	° ′
(1) Nebula in Andromeda	—	Greenish-white.	0 35 4	+40 30·14
(2) γ Cassiopeiæ	2	Bluish-white.	0 50 1	+60 7
(3) 47 Piscium	5	Yellowish-red.	0 42 58	+ 6 59·2
(4) ι Ceti	3	Yellowish-white.	0 13 48	− 9 26
(5) γ Pegasi	3	White.	0 7 34	+14 34
(6) D.M. + 34° 55′	8	Deep red.	0 21 42	+34 53
(7) T Herculis	Var.	Reddish.	18 4 56	+31 0

Remarks.

(1) Dr. Huggins notes that the spectrum ends abruptly in the orange. Maxima of brightness have since been recorded by myself at, approximately, 468–474, 517, and 546, and the latter two have also been confirmed by Mr. Taylor. Further confirmation is required. For comparison, a Bunsen or spirit-lamp flame will be found convenient for the first two, and the brightest fluting seen when lead chloride is introduced into the flame for the third. Mr. Lockyer suggests that since the central condensation is probably at a higher temperature than the surrounding portions of the nebula, different parts of the nebula should show differences in their spectra. Observing with Mr. Lockyer's 30-inch reflector at Westgate-on-Sea, on October 20, I suspected some change in the spectrum away from the nucleus, but was unable to complete the observation on account of clouds, and have not since had an opportunity of repeating it.

(2) The bright lines most constantly seen in the spectrum of this star are C, F, and D_3, but their appearance is somewhat irregular. Continuous observations, with special reference to the relative intensities of the lines, are suggested. The lines are well seen in a 10-inch equatorial with a Maclean spectroscopic eye-piece. Bright flutings of carbon have also been suspected, and comparisons should be made with the Bunsen or spirit-lamp to confirm these. The continuous spectrum should also be carefully examined for maxima. *b*, D, and other absorption-lines, have also been recorded.

(3) This is a star which gives a spectrum of dark flutings fading away towards the red. Dunér records bands 2 to 9, and describes the spectrum as superb. Band 3, near D, is of extraordinary width. The spectra of this type have been explained as mixed metallic fluting absorption and carbon fluting radiation. The carbon flutings probably present are 517 and 468–474, which again may be determined by comparison with the spirit-lamp, 517 being the brightest green fluting.

Dunér's notation and mean wave-lengths of the dark bands are as follows:—(1) 648–666, (2) 616·2–629·8, (3) 586·7–596·8, (4) 559·8–564·9, (5) 545·2–551·5, (6) 524·3–528·1, (7) 516·8–522·2, (8) 495·9–503·0, (9) 476·0–483·0, (10) 460·7–473. The bright spaces between 7 and 8, and 9 and 10 are probably due to carbon.

(4) This is a star of Class II.*a*, which is now divided into two groups, one having spectra of the type of α Tauri (Group III.), and the other of the sun (Group V.). The lines should be carefully observed, and differences from the solar spectrum, if any, noted, so that the star can be classed in one group or the other. The principal criteria so far determined for Group III. are strong lines at 499 and 540, 568 and 579. The line at 540 forms with E (5268), and the iron line at 5327 (both solar lines), an equi-distant trio. The difference between the two groups may perhaps best be observed by a comparison of Aldebaran and Capella.

(5) The spectrum of this star is Class I.*a* (Group IV.). The relative intensities of the hydrogen and metallic lines should be noted, in order that the star may be arranged with others in order of temperature.

(6) Dunér gives the spectrum of this star as Class III.*b* (Group VI.), in which the main features are three dark carbon flutings fading away towards the blue. Other absorptions, if any, should be carefully observed, and their relative intensities recorded.

(7) This is a variable star, which reached its maximum on November 6. The magnitude at maximum is given by Gore as 6·9–8·3, and the period as 165·1 days. The spectrum has not yet, so far as I know, been recorded.

A. FOWLER.

GEOGRAPHICAL NOTES.

THE telegrams in the papers of Monday and Tuesday from Mr. Stanley are of the most suggestive and interesting character. For one thing, Emin, Casati, and others who have been holding out, are safe, though the brave Pasha has evidently been deserted by most of his men. That Mr. Stanley's expedition was needed the result has proved. He reached the Albert Nyanza for the third time, not a moment too soon to rescue the retreating party. We need not dwell on the sacrifices that have been entailed; they might to some extent have been avoided, but personally Mr. Stanley is not to blame. The geographical results of the expedition, as shadowed in the too brief telegram in Tuesday's papers, are evidently of the highest interest. There is now no doubt that there is a southern Albert Lake, Muta Nzigé, which Mr. Stanley has named Lake Albert Edward. From the time when he himself discovered what he called Beatrice Gulf until the present, no one had seen this lake. At first it was thought to be a part of the northern lake, Albert Nyanza, but that idea had to be given up. Now it is clear that it is connected with that lake by the River Sempliki. The southern lake is 900 feet higher than the northern, and so is about 3200 feet above sea-level, and 450 feet above Lake Tanganyika, with which it is unlikely to have any connection. Mr. Stanley skirted the snowy mountain range referred to in his letters of six months ago, and found that they send down fifty streams to feed the

[1] Roy. Soc. Proc., vol. xlv. pp. 380–392.

Sempliki. Awamba, Usongora, Toro, Ahaiyama, Unyampaka, and Anhori, are all districts around the west, north, and east shores of the Lake Albert Edward, three sides of which Mr. Stanley says he has traversed—probably the east, west, and north sides, though it is possible he may have gone round the south side. It is probable that the lake as laid down on our maps is much too large, and that it is comparatively small. Mr. Stanley found it to be 15 miles wide at Beatrice Gulf. From the lake he struck south-east to Karagwe and Uzinze, on the south-west and south of Victoria Nyanza, and no doubt found at Mslala the stores which have been accumulating for many months. Thus it will be seen Mr. Stanley has solved one of the few remaining problems of African geography. He has found the south-west source of the Nile, and established the true relations which exist among the great lakes of Central Africa. He has filled up an important blank in our maps, and collected observations which will enable us to understand the physical geography of one of the most interesting regions on the continent. Probably he will be able to tell us what has become of the Alexandra Lake of his former expedition. It may be as well to state that the telegram of Monday was in effect the first part of that of Tuesday, and therefore Emin's safety was not again referred to in the latter.

THE Zanzibar Correspondent of the *Times* telegraphed on November 5 that authentic news had reached Lamu that Dr. Peters and the whole of his party had been massacred, except one European and one Somali, wounded, who are at Ngao. Some say they were killed by Masais, and some by Somalis.

FROM the Journal of the Anthropological Society in Vienna, we take the following conclusions of Dr. B. Hagen, respecting the Malay peoples:—Their great predilection for the sea, which makes them pray to Allah that they may die on sea, seems to render the Malay race adapted for the Polynesian and Further Indian Archipelago. The centre from which they migrated is to be sought in the highlands of West Sumatra, particularly in the old kingdom of Menang-Kabau. Thence the peoples extended slowly eastwards; at first probably the races now to be found only in the interior of the great islands (the Battas in Sumatra, the Sundanese in Java, the Dayaks in Borneo, the Alfurus in Celebes, &c.). These "aborigines" of the islands crushed out a population already in possession, as remains of which the Negritos may be taken. The Malays in the narrower sense occupying Sumatra, Malacca, and North Borneo, are to be regarded as the last emigration from the centre referred to, occurring from the twelfth to the fifteenth century A.D. With the Indians and Chinese, who have been long in intercourse with the archipelago, arose mixtures and crosses, in less measure also with the Arabs. One must not therefore expect the pure racial type, especially in the coast population. The crania of the anthropological collections are too imperfectly determined in respect of their *locale* to be of any service for a judgment of the Malay peoples. Of more value are the measurements of the living begun by Dr. Weisbach and executed by Dr. Hagen in 400 cases. The latter's conclusions are:—(1) The peoples in the interior of Sumatra—the Battas, the Allas, and the Malays of Menang-Kabau—compose a closely allied group always in direct contrast with the hither-Indian peoples, and yet showing just as little community with the Chinese. We must therefore take them for the pure original type, characterizable as follows:—Small, compact, vigorous figure of less than 1600 mm. average size; long arms; very short legs; very long and broad mesocephalous skull of very great compass, with high forehead; a prognathous face 10 per cent. broader than long, with large mouth, and uncommonly short, flat, and broad nose with large round nostrils opening mostly frontwise, and with broad nasal root. (2) The Malays of the east coast of Sumatra and those of the coasts of Malacca indicate a much greater affinity to the Indians than to their tribal peoples of Menang-Kabau. They are plainly therefore thoroughly mixed with Indian blood. (3) The Javanese peoples stand much nearer to the original type of the Sumatrans than to the Malays just mentioned. They show therefore less mixture with Indian, but on the other hand more mixture with Chinese, blood, and the Javanese more so than the Sundanese.

THE second number of this year's "Information respecting Kaiser Wilhelmsland and the Bismarck Archipelago," issued by the German New Guinea Company, contains a description of the north coast of New Guinea, from Cape Cretin to the Legoarant Islands, by the former Governor, Vice-Admiral Freiherr von Schleinitz, with a map designed by him. According to this account, Kaiser Wilhelmsland is subject to the south-east trade wind. This is, however, occasionally relieved by the opposite wind, when, viz., the sun in southing imparts to the Australian continent a temperature higher than that of New Guinea. The temperature, averaging 26° to 27° C., is not so high as might be inferred from the equatorial situation of the land, a fact due in part to the prevalence of the trade wind, which also brings with it a cooling sea-current to the coast, and in part to the considerable elevation of most of the island. The north-west, blowing especially from January to April, comes on the whole with greater force than the south-east. Calms often occur from March to May and from October to December. Precipitation is on the whole copious, but there are many differences according to the local variations in the configuration of the land. The navigation of the coast offers no particular dangers and difficulties, either for steamers or sailing-vessels. Serious storms are extremely rare, nor are there any reefs in the channel proper. Sea currents do not strike direct on the coast, and they are not generally very strong. The tides are inconsiderable, the spring floods keeping under 1 metre.

SOME interesting remains have been found in Hamburg on the site of the new Rathhaus. At a depth of 0 to 0·7 metre the ground was covered to a height of 10 to 15 centimetres with dams of thin willow twigs (*Salix fragilis*), in many places two, sometimes even three, layers above one another, and separated from one another by equally thick earth layers. The building rests on clay, *i.e.* submerged ground, which contained heaps of freshwater shells, *e.g.* *Valvata piscinalis*, *Bythinia tentaculata*, &c., as also *Cardium edule*, *Tellina baltica*, *Mactra solida*, &c. When therefore the dam was made, the water must have been strongly brackish. The interest in this discovery was heightened when there was found, under St. Anne's Bridge, at a depth of 0·5 metre, a regularly paved street of small boulders, such as were still used for stone pavement in all North German towns in the last century. The stone dam was about 5 metres broad, and encased on both sides by thick wooden planks, in order, in the swampy ground, to prevent the slipping out of the stones sideways. The ascertained changes in the level of the North Sea give no positive clue to the age of the Hamburg finds.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

ON Monday evening the first annual dinner of the Institution of Electrical Engineers took place at the Criterion Restaurant, Sir William Thomson, the President, occupying the chair. Many different branches of science were represented on the occasion, and some of the after-dinner speeches rose to a high level of excellence.

Due honour having been done to the usual loyal toasts, and Major Webber and Captain Wharton having responded for the Army and Navy, the Chairman proposed "Her Majesty's Ministers." Lord Salisbury said, in response:—

Sir William Thomson and Gentlemen,—I have to thank you on behalf of my colleagues in the Goverment and myself for the exceedingly kind reception you have given to the kind words in which Sir William Thomson has proposed this toast. I do not feel that I can accept the guise in which he put my name forward. On the contrary, though recognizing, as every individual must do, and as I have especial reason to do, the enormous benefits which electrical science confers upon mankind, I feel that I have reason rather to apologize for my appearance in this assembly. When I look round on so many learned and distinguished men, I feel rather in the position of a profane person who has got inside the Eleusinian mysteries. But I have an excuse. The gallant gentlemen who replied for the Army and Navy were able to show many particulars in which their special professional vocation was sustained and pushed forward by the discoveries of electrical science. But I will venture to say that there is no department under the Government so profoundly indebted to the discoveries of those who have made this science as the Foreign Office, with which I have the honour to be connected. I may say that we positively exist by virtue of the electric telegraph. The whole

work of all the Chancelleries in Europe is now practically conducted by the light of that great science, which is not so old as the century in which we live. And there is a strange feeling that you have in communicating constantly and frequently day by day with men whose inmost thoughts you know by the telegraph, but whose faces you have never seen. It is something more than a mere departmental effect which these great discoveries have had upon the government of the world. I have often thought that if history were more philosophically written, instead of being divided according to the domination of particular dynasties or the supremacy of particular races, it would be cut off into the compartments indicated by the influence of particular discoveries upon the destinies of mankind. Speaking only of these modern times, you would have the epoch marked by the discovery of gunpowder, the epoch marked by the discovery of the printing-press, and you would have the epoch marked by the discovery of the steam-engine. And those discoveries have had an influence infinitely more powerful, not only upon the large collective destinies, but upon the daily life and experience of multitudes of human beings, than even the careers of the greatest conquerors or the devices of the greatest statesmen. In that list which our ignorance of ancient history in its essential character forbids us to make as long as no doubt it might be made, the last competitor for notice and not the least would be the science of electricity. I think the historian of the future when he looks back will recognize that there has been a larger influence upon the destinies of mankind exercised by this strange and fascinating discovery than even in the discovery of the steam-engine itself, because it is a discovery which operates so immediately upon the moral and intellectual nature and action of mankind. The electric telegraph has achieved this great and paradoxical result, that it has, as it were, assembled all mankind upon one great plane where they can see everything that is done, and hear everything that is said, and judge of every policy that is pursued at the very moment when those events take place; and you have by the action of the electric telegraph, combined together almost at one moment, and acting at one moment upon the agencies which govern mankind, the influences of the whole intelligent world with respect to everything that is passing at that time on the face of the globe. It is a phenomenon to which nothing in the history of our planet up to this time presents anything which is equal or similar, and it is an effect and operation of which the intensity and power increases year by year. When you ask what is the effect of the electric telegraph upon the condition of mankind, I would ask you to think of what is the most conspicuous feature in the politics of our time, the one which occupies the thoughts of every statesman, and which places the whole future of the whole civilized world in a condition of doubt and question. It is the existence of those gigantic armies held in leash by the various Governments of the world, whose tremendous power may be a guarantee for the happiness of mankind and the maintenance of civilization, but who, on the other hand, hold in their hands powers of destruction which are almost equal to the task of levelling civilization to the ground. What gives these armies their power? What enables them to exist? By what power is it that one single will can control these vast millions of men and direct their destructive energies at one moment on one point? What is the condition of simultaneous direction and action which alone gives to these vast armies this tremendous power? It is nothing less than the electric telegraph. And it is from that small discovery, worked out by a few distinguished men in their laboratories upon experiments of an apparently trivial character, on matter and instruments not, in the first instance, of a very recondite description—it is on that discovery that the huge belligerent power of modern States, which marks off our epoch of history from all that have gone before, must be held, by anyone who investigates into the causes of things, absolutely to depend. I would venture to hope that this is not all, in its great effect upon the history and government of our race, that electricity may achieve. Whether it so far is good or evil in the main, it must be for the future to determine. We only know that the effect, whatever it is, will be gigantic. But in the latter half of the short life of this young science another aspect of it has been developed—an aspect which I cannot help hoping may be connected with great benefits to the vast community of industrious and labouring men—I mean that facility for the distribution of power of which electricity has given such a splendid instance. The event of the last century was the discovery of the steam-engine. But the steam-engine was such that the forces which it produced could only act in its own immediate neighbourhood, and therefore those who were to utilize its forces and translate them into practical work were compelled to gather round the steam-engine in vast factories, in great manufacturing towns, and in great establishments where men were collected together in unnatural, and often unwholesome, aggregation. Now an agent has been discovered, by which the forces of the steam-engine, stiff, confined to its own centre, can be carried along, far away from its original sources, to distances which are already great, and which science promises to make more considerable still. I do not despair of the result that this distribution of forces may scatter those aggregations of humanity, which I think it is not one of the highest merits of the discovery of the steam-engine to have produced. If it ever does happen that in the house of the artisan you can turn on power as now you can turn on gas—and there is nothing in the essence of the problem, nothing in the facts of the science, as we know them, that should prevent such a consummation from taking place—if ever that distribution of power should be so organized, you will then see men and women able to pursue in their own homes many of the industries which now require the aggregation at the factory. You may, above all, see women and children pursue these industries without that disruption of families which is one of the most unhappy results of the present requirements of industry. And if ever that result should come from the discoveries of Oersted and Faraday, you may say that they have done more than merely to add to the physical forces of mankind. They will have done much to sustain that unity, that integrity of the family, upon which rest the moral hopes of our race and the strength of the community to which we belong. These are some of the thoughts which electricity suggests to one of my trade. Pardon me if I have wandered into what may seem to be speculative and unfamiliar fields. But, after all, the point of view from which we must admire the splendid additions to our knowledge which the scientific men of the world, and especially of England, during this century have made, is, that they have enabled mankind to be more happy, to be more contented, and therefore to be more moral.

Sir Frederick Abel proposed, and Sir George Gabriel Stokes responded for, "The Learned Societies"; and Sir John Coode responded for the toast of "The Professional Societies," which was proposed by Mr. Latimer Clark. The toast of "The Institution of Electrical Engineers" was then proposed by Lord Salisbury. In the course of his response, Sir William Thomson said:—

One very remarkable piece of work they should think of especially this year, and during the last few weeks, when they deplored the loss of one of the greatest workers in electrical science and its practical application that the world had ever seen—Joule. The great scientific discoveries of Faraday, which were prepared almost deliberately for the purpose of allowing others to turn them to account for the good of man, had been going on for about fifteen years, when a young man took up the subject with a profound and penetrating genius most rare in any branch of human study, and perceived relations with mechanical power which had never been suspected before. Joule saw the relations between electricity and force, and his very first determination of the mechanical equivalent was an electrical measurement. His communication to the British Association, when it met in Cork in the year 1841, pointed out for the first time the distinct mechanical relation between electric phenomena and mechanical force. Joule was not a mere visionary who saw and admired something in the air, but he pursued what he saw to the very utmost practical point of work, and he it was who determined the mechanical equivalent of heat. Afterwards he thoroughly confirmed the principle of his first determination of the mechanical equivalent of heat. Both in electricity and mechanical action he laid the foundation of the great development of thermodynamics, which would be looked upon in future generations as the crowning scientific work of the present century. It was not all due to Joule, but he had achieved one of the very greatest monuments of scientific work in the present century. For an Institution of Electrical Engineers it was interesting to think that the error relating to one of the most important electrical elements, the unit of resistance (now called the ohm), as determined electrically in the first place by a Committee of the British Association, and by purely electrical method, was first discovered by Joule's mechanical measurement. It was Joule's mechanical measurement which first corrected the British Association unit, and gave the true ohm.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following examiners have been appointed: Natural Sciences Tripos: Physics, Prof. Carey Foster and W. N. Shaw; Chemistry, Prof. W. A. Tilden and Prof. Liveing; Mineralogy, Prof. Lewis and L. Fletcher; Geology, Prof. Green and W. W. Watts; Botany, F. Darwin and D. H. Scott; Zoology, Prof. Lankester and S. F. Harmer; Human Anatomy, Drs. Hill and Windle; Physiology, Prof. Stirling and C. S. Sherrington.

First M.B. and Special B.A.: in Elementary Physics, S. L. Hart and H. F. Newall; Elementary Chemistry, F. H. Neville and S. Ruhemann; Elementary Biology, S. F. Harmer and Prof. H. M. Ward; Special B.A. in Geology, Prof. Green and W. W. Watts; in Pharmaceutical Chemistry for Second M.B., M. M. Pattison Muir and H. Robinson.

The following are Moderators (Mathematical Tripos) for the year beginning May 1, 1890:—W. W. R. Ball and A. J. Wallis. Examiners in Part I., W. L. Mollison and E. G. Gallop; in Part II., Prof. Darwin, J. Larmor, and R. Lachlan.

W. B. Hardy, of Gonville and Caius College, has been appointed Junior Demonstrator of Physiology.

L. R. Wilberforce, M.A., of Trinity College, is approved as a Teacher of Physics for M.B. lectures.

There has been a serious discussion of the financial management and prospects of the mechanical workshops at Cambridge. Whatever be the merits of the points in dispute, such division of opinion and feeling is very unfortunate, and much to be deplored in the interests of mechanical science and engineering in the University. It was unfortunate that the University declined to establish an advanced examination or Tripos in engineering subjects; and it is calamitous that the Museums work should not be given to the Department located within their own borders. We trust a cordial understanding may soon be re-established; for this division is very unlike the strong action by which, even when opinions have been divided, scientific teaching has steadily progressed of late years at Cambridge.

The managers of the John Lucas Walker Fund, have made the following grants in aid of original research in pathology:—£14 2s. 3d. to J. G. Adami, Demonstrator of Pathology, for expenses of his investigations on the pathology of the heart; £35 to William Hunter, M.D. Edin., John Lucas Walker Student, to defray expenses incurred in his research on the pathology of the blood; £30 to E. Hanbury Hankin, to defray expenses of his research on the nature of immunity from infectious diseases.

Mr. J. W. Clark has been re-elected President of the Philosophical Society.

ST. JOHN'S COLLEGE.—At the annual election of Fellows, on Nov. 4, the choice of the Council fell upon the following members of the College: John Parker, Seventh Wrangler, 1882, well known as the author of numerous papers, in the *Philosophical Magazine* and elsewhere, on thermodynamics and electricity; Humphry Davy Rolleston, First Class Natural Sciences Tripos (Human Anatomy and Physiology), 1886, who has been University Demonstrator in Pathology, in Human Anatomy, and in Physiology, author of memoirs on endocardiac pressure and on other anatomical, physiological, and pharmacological subjects, now one of the Assistant Demonstrators of Anatomy at St. Bartholomew's Hospital; Alfred William Flux, bracketed Senior Wrangler, 1887, and First Class (Division 1) Mathematical Tripos, Part II., 1888, Marshall Prrizeman in Political Economy, 1889, author of papers on physical optics. Mr. Rolleston is the son of the late Prof. Rolleston, of Oxford. The success of students of physical and biological science at this College is striking.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 28.—M. Des Cloizeaux, President, in the chair.—M. Bertrand presented a volume entitled "Lectures on the Mathematical Theory of Electricity, delivered at the College of France."—On some hybrids observed recently in Provence, by M. G. De Saporta. Three are described: (1) between *Pinus halepensis*, Mill., and *P. pinaster*, L.; (2) between *Quercus Mirbeckii* and *Q. pubescens*, Wild.; (3) between *Tilia platyphylla*, Scop., and *T. argentea*, Desf.; in each case, the pollen of a preponderating species acting on that of a subordinate one, or one accidentally introduced, being carried by wind or insects, while the agency of man, birds, or wind, disseminated the hybrid seeds.—On the relation of certain magnetic perturbations to earthquakes, by M. Mascart. The former, in the Park of St. Maur, and the latter, at Gallipoli, seem to have occurred simultaneously at 11.35 p.m. on October 25. The suspended copper bar was not in the least deflected, and the magnetic disturbance cannot be attributed to mechanical transmission of the shock.—On certain harmonic linear elements, by M. Raffy.—On a formula connecting vapour-pressure with temperature, by M. N. de Saloff.—On the equilibrium of distribution between chorine and oxygen, by M. H. Le Chatelier. He shows that the value of all the coefficients may be calculated *a priori*, and supplies the required formulæ.—On some double nitrites of ruthenium and potassium, by MM. A. Joly and M. Vèzes. In contact with alkaline nitrites, the brown sesquichloride of ruthenium is transformed into a red salt. According to the temperature, and according as the nitrite or the red chloride predominate, a deposit is formed either of yellow crystalline powder, sparingly soluble in cold water, or of large, very soluble orange-red crystals. These two substances are double nitrites of potassium and ruthenium. The formulæ obtained do not at all agree with those for similar compounds obtained by Claus.—Fixation of nitrogen by the Leguminosæ, by M. Bréal. Having before found that nodosities full of Bacteria could be easily produced on the roots of a leguminous plant, by pricking with a needle previously inserted in a nodosity, he here shows that such plants, with nodosities, flourish on soil poor in azotized matter; yielding crops rich in nitrogen, and fixing this element in the soil by their roots.—On air in the soil, by M. Th. Schlœsing, *fils*. Ploughed land was found to contain a relatively large amount of oxygen at least to the depth of 50 or 60 cm. The carbonic acid generally increased with the depth; but in two cases the reverse occurred, when high wind (renovating the upper layer) had been followed by hot and calm weather, and more CO_2 was generated in the soil than in the sub-soil. In sloping pastures, most CO_2 was found at the bottom. The mobility of air in the soil should be taken into account.—On sorbite, by MM Vincent and Delachanal. This substance very frequently occurs in nature; it is found in all fruits of Rosaceæ, and is especially abundant in pears (8 grammes per kilogramme), cherries and prunes (7 grammes). Acted on by hydriodic acid it yields β-hexylene and other products (the same as are thus obtained from mannite). The formation of a hexacetyl derivative from sorbite proves that it is a hexatomic alcohol. The formula of anhydrous sorbite is $C_6H_8(OH)_6$.—Researches on crystallized digitaline, by M. Arnaud. He regards it as a definite chemical species; and it appears to be the type of a whole series, including tanghinine (one of the active principles of the tanguin.—Experimental researches on the metamorphosis of Anoura, by M. E. Bataillon. He finds acceleration of the rhythm of respiration (65 to 120), and retardation of that of the heart (70 to 45) during metamorphosis. Before appearance of the fore-legs, the two movements were nearly synchronous. At the stage of this appearance, further, the production of carbonic acid was found to have diminished considerably, and the curve rose suddenly when aërial respiration was established.—On the earthquake of July 28, 1889, in the island of Kiushiu, in Japan, by M. J. Wada. This was preceded by exceptional rains during July. The longer axis of the ellipse of land affected was north-east to south-west, and cut in the middle, at right angles, the line joining two volcanoes, 100 kilometres apart.

BERLIN.

Physiological Society, October 18.—Prof. du Bois-Reymond, President, in the chair.—Prof. Kossel spoke on the application of the microscope in connection with physiological chemistry. It has long been the practice to seek for and identify any minute crystals in tissues which occur either naturally or as the result of treatment with reagents, in order to arrive at a qualitative determination of the localized distribution of certain well-known substances in the organism. To identify a crystal by measurement of its angles is a laborious process, and to determine it by mere comparison of its appearance with drawings of known crystals is insufficient. The optical properties of crystals are extremely well adapted to assist in their identification; this is exemplified in the case of determining the plane of vibration of the ordinary and extraordinary rays when crystals are examined between crossed Nicols. To carry out the determination by this means, the field of view of the microscope is provided with cross-wires,

whose directions are parallel to the principal planes of the two Nicols. The crystal under examination is then placed with one edge under one of the cross-wires; if the field of vision remains dark, then the planes of vibration in the crystal are known to correspond to the chief planes of the two Nicols. If, however, the field of vision becomes bright the crystal must be rotated, by means of a graduated object-carrier until it is again dark. The angle through which the carrier has been rotated is a measure of the angular inclination of the planes of vibration to the edges of the crystal. When convergent polarized light is used, the majority of crystals of organic substances, which are mostly biaxial, exhibit a lemniscate whose poles are at varying distances apart for various crystals. The distance between the poles of the lemniscate may be measured by suitable methods, is extremely characteristic for those crystals of greatest physiological importance, and may be used, in conjunction with the measurement of the planes of vibration, as a very certain means of determining the crystal. The pleochromatism of many crystals is itself in many cases sufficiently characteristic.—Dr. Virchow described the distribution of blood-vessels in the eye of Selachians, and the several types according to which the vessels are developed in the eyes of various classes of animals.—Dr. Benda made a communication to the effect that the coiled glands which are so widely distributed as sweat-glands in the skin when they exhibit an enlarged secretory part, and a more complicated structure, are known as cerumenous and as mammary glands. They are characterized specially by the fact that during secretion there is no destruction of their epithelium. These modifications of the typical coiled glands have been found by Dr. Benda in large numbers and widely spread in the skin of Protopterus.—Dr. Schneider spoke on the distribution and significance of iron in the animal organism. He was able to find iron in greater or less quantity in the cell-protoplasm and nucleus of all classes of animals, the liver and spleen being the organs in which its occurrence was most marked. The connective tissues were very rich in iron, and it was found with similar constancy in the cuticular layers and quite constantly in the extreme tips of fishes' teeth. The more he extended his investigations over the most widely differing classes of animals, whether on land, or in fresh-water, or in the sea, and the more widely different were the organs he examined, by so much the more was it seen that iron is universally present in the animal organism. Its importance is pre-eminently physiological.

AMSTERDAM.

Royal Academy of Sciences, September 28.—Prof. van der Staals in the chair.—M. Suringar dealt with the Melocacti of Aruba, stating what he had himself observed concerning the development of those plants from seed and their subsequent growth. He spoke also of the manner in which the Melocacti might be classified according to their natural affinities, and sketched a pedigree of the species.—M. Schoute spoke of tetrahedra, bounded by similar triangles, and described a new species with pairs of opposite edges 1 and r^3, r and r, r^2 and r^2.

STOCKHOLM.

Royal Academy of Sciences, October 9.—Musci Asiæ Borealis (second part): feather mosses, by the late Prof. S. O. Lindberg, of Helsingfors, and Dr. H. W. Arnell.—On the permanent committee for a photographic map of the heavens and its work, by one of its members, Prof. Dunér.—On the Metre Congress in Paris, September 14–28, this year, and on the prototypes of the metre and the kilogramme, by Prof. Thalén.—Emanuel Swedenborg as a mathematician, by Dr. G. Eneström.—On naphtoë acids, by Dr. A. G. Ekstrand.—Chemical investigation of some minerals from the neighbourhood of Langesund, by Herr H. Bäckström.—An attempt to determine the velocity of light from observations on variable stars, by Dr. C. Charlier.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, NOVEMBER 7.

LINNEAN SOCIETY, at 8.—On a Collection of Dried Plants chiefly from the Southern Shan States, Upper Burma: Colonel H. Collett and W. Botting Hemsley, F.R.S.

CHEMICAL SOCIETY, at 8.—The Isolation of a New Hydrate of Sulphuric Acid existing in Solution: S. U. Pickering.—Further Observations on the Magnetic Rotation of Nitric Acid, of Hydrogen Chloride, Bromide and Iodide in Solution: Dr. W. H. Perkin, F.R.S.—On Phosphoryl Trifluoride: T. E. Thorpe, F.R.S., and F. T. Hambly.—On the Acetylation of Cellulose: C. F. Cross and E. Bevan.—On the Action of Light on Moist Oxygen: A. Richardson.—Anhydracetophenonebenzil and the Constitution of Linius lepideus: Drs. Japp, F.R.S., and Klingeman.

FRIDAY, NOVEMBER

ROYAL ASTRONOMICAL SOCIETY, at 8.

MONDAY, NOVEMBER 11.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Cyprus: Lieut.-General Sir Robert Biddulph, G.C.M.G.

TUESDAY, NOVEMBER 12.

ANTHROPOLOGICAL INSTITUTE, at 8.30.—Observations on the Natural Colour of the Skin in certain Oriental Races: Dr. J. Beddoe, F.R.S.—Manners, Customs, Superstitions, and Religions of South African Tribes: Rev. James Macdonald.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Inaugural Address of Sir John Coode, K.C.M.G., President, and Presentation of Medals, Premiums, and Prizes awarded during Last Session.

WEDNESDAY, NOVEMBER 13.

ROYAL MICROSCOPICAL SOCIETY, at 8.

THURSDAY, NOVEMBER 14.

MATHEMATICAL SOCIETY, at 8.—Isoscelian Hexagrams: R. Tucker.—On Euler's ϕ-Function: H. F. Baker.

FRIDAY, NOVEMBER 15.

PHYSICAL SOCIETY, at 5.—On the Electrification due to the Contact of Gases and Liquids: J. Enright.—On the Effect of Repeated Heating and Cooling on the Electrical Resistance and Temperature Coefficient of Annealed Iron: H. Tomlinson, F.R.S.—Notes on Geometrical Optics, Part II.: Prof. S. P. Thompson.

INSTITUTION OF CIVIL ENGINEERS, at 7.30.—The New Harbour and Breakwater at Boulogne-sur-Mer: S. C. Bailey.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

A Popular Treatise on the Winds: W. Ferrel (Macmillan).—South African Butterflies; vol. iii., Papilionidæ and Hesperidæ: R. Trimen and J. H. Bowker (Trübner).—Light, 2nd edition: P. G. Tait (Edinburgh, Black).—The Vertebrate Animals of Leicestershire and Rutland: M. Browne (Birmingham, M. E. C.).—Sitzungsberichte der k. b. Gesellschaft der Wissenschaften Math.-Naturw. THURSDAY, NOVEMBER 14, 1889.

SCIENCE AND THE FUTURE INDIAN CIVIL SERVICE EXAMINATIONS.

THE following memorial, signed by a numerous and highly-distinguished body of resident graduates of the University of Cambridge, has been presented to the Civil Service Commissioners:—

"We, the undersigned resident graduates of the University of Cambridge interested in the study of natural science, understanding that a reorganization of the open competitive examination for the Civil Service of India is under the consideration of the Civil Service Commissioners, beg respectfully to urge on the Commissioners the desirability of widening the range of the examination so as to include the several branches of natural science. We think it especially important that the maximum number of marks obtainable by a candidate in natural science in the examination should be the same as that obtainable by a candidate in classics or in mathematics. In support of this opinion we venture to point out that the Natural Sciences Tripos, both from its numbers and from the rewards assigned by the Colleges to those of their members who distinguish themselves therein, is now of equal importance with the Classical or Mathematical Tripos.

"We have the honour to append a statement of the numbers who have during the last five years taken honours in natural science, classics, and mathematics. We inclose a copy of the *Cambridge University Reporter* of June 12, 1888, containing a report to the Senate and a schedule of the numbers examined in each branch of natural science in the years 1883–87.

"We would desire to call attention to the acknowledged educational value of the study of natural science, and to point out that the training which it affords, combining as it does both theory and practice, is such as peculiarly to fit a student for the pursuits of practical life.

"We beg to state that a deputation would be happy to wait on the Commissioners to explain more fully our views on the subject should it be their pleasure to receive them."

This memorial is signed, among others, by two Heads of Houses, thirteen Professors, and twenty Fellows. The memorialists, as will be seen, urge that in future competitions the position of a candidate offering natural science shall be not less favourable than that of those who offer classics or mathematics. And in a highly instructive schedule they show how important a place the study of the natural sciences has now attained in the University of Cambridge.

It may be unknown to many of our readers that the subject to which this memorial relates has lately become one of great importance, in consequence of a proposed reorganization of the higher branches of the public services in India. A Commission, which we believe sat in India, known as the Public Service Commission, has advised that the following changes should be made with the object of admitting natives of India to higher and more extensive employment in the public services:—

(1) That the strength of the Covenanted Civil Service should be reduced to what is necessary to fill the chief administrative appointments of the Government, and such a proportion of smaller appointments as will secure a complete course of training for junior Civilians. This branch of the service to continue to be recruited by means of open competitions in England, at which natives of India should be allowed to compete unreservedly, and for which the maximum age of the Native candidates, and therefore presumably of the English candidates, should be raised to twenty-three years.

(2) That a certain number of appointments should be transferred from the Covenanted Civil Service to a local Civil Service, which is to be recruited, locally, from Natives and resident Europeans who satisfy certain prescribed preliminary conditions.

We do not know how far these proposals have been adopted by the home authorities, though we understand that they have received the general approval of the Indian Government. We will therefore only say, in passing, that they appear to be open to two serious objections.

First, that it seems a dangerous thing to select so limited a number of young men for the higher branch of the service by open competition, since doing so will give to each one of those who succeed almost the certainty of the reversion of one of the prizes of the public services. Under such a condition there will be far too little inducement for zeal in the service, and too little opportunity for selection and rejection when age and experience have developed the administrative powers of the selected men.

Secondly, unless care be taken to regulate the previous training of the candidates, as, for example, by requiring that every candidate shall have taken a University degree in England or India before presenting himself at the competitive examination, it is likely that well-taught rather than well-educated men will be selected, and that an inferior order of men will offer themselves, since many of the ablest men would be unable to submit to some years of private tuition, and to give up, as they would probably have to do, a University education for the chance of obtaining an appointment in India.

Whatever decision may have been made, however, it is of the utmost importance that the representatives of Cambridge who have addressed themselves to the Civil Service Commissioners should be supported in every possible way, and at once, by all those who have the interest of science and education at heart. For there is reason to fear that the Commissioners have contemplated the complete withdrawal of science from these examinations; and unfortunately many of the various regulations for the Army examinations which have been brought forward with their sanction in recent years give an air of probability to this suggestion. This is in no way weakened when we consider the extremely unfortunate position that science candidates for the Indian Civil Service have occupied under the administration of the Commissioners for many years past. This position, it should be said, has been due, not so much to the marks allotted to science in the present scheme, as to the methods adopted by the Commissioners in conducting their examinations, which have long caused it to be recognized by those who are engaged in the instruction of Civil Service candidates that, as a rule, only those candidates who are excellent either in classics or mathematics, or those who are distinctly good in both, have a really good chance of success.

But though all these facts give reason for regarding the rumour we refer to as very possibly correct, they need by no means prevent those who are interested in the question from entertaining strong hopes of averting such a national disaster as that which we fear. We have only to remind them of the very considerable degree of success that followed the efforts recently made by Sir Henry Roscoe and other leaders in science in the case of the examinations for admission to the Royal Military Academy at Woolwich. These efforts, we may remind our readers, not only resulted in an advantageous revision of the Woolwich examinations, but brought about satisfactory changes in the case of the Sandhurst competitions. In connection with this result it is satisfactory to observe, in the Report of the Civil Service Commission for 1888, that the Commission, in a letter directed to the Director-General of Military Education on July 10 in that year, have described the changes that had been submitted to them as likely to influence beneficially the education of officers in the army before they begin their professional studies.

Whatever difficulties there may be in the way of obtaining just treatment for science candidates under the new scheme for the selection of Indian civil servants, it has, we fear, become again imperative that men of science should unite to protest against the assumption that natural science studies are in themselves inferior as a mental training to the classical languages and mathematics, and to insist, so far as they may, upon such studies being placed upon a proper footing in this particular examination. This should be done in the interests of education, and still more of our Indian fellow-subjects, whose administrators should be men of as wide and liberal an education as possible, as has, indeed, been recognized in more than one public investigation of the regulations for these appointments.

THE LUND MUSEUM IN THE UNIVERSITY OF COPENHAGEN.

E Museo Lundii: En Samling af Afhandlinger om de i det indre Brasiliens Kalkstenshuler af Professor P. V. Lund udgravede Dyre-og Menneskeknogler. Udgivet af Dr. Lütken. (Kjöbenhavn: H. Hagerup, 1888.)

THIS work, as its title indicates, consists of various monographs, descriptive of the collections made by Dr. Lund in his interesting exploration of the limestone caverns in the interior of Brazil. These important finds are the fruits of nearly ten years' unremitting labour in the neighbourhood of Lagoa Santa, on the Rio das Velhas, in the province of Minas Geraes, where Dr. Lund prosecuted his researches from 1835 to 1844. On the completion of his cave explorations he presented the whole of his incomparable collections to the Danish nation. The gift has been duly appreciated, and now constitutes, under the name of the "Lund Museum," one of the most important palæontological sections of the Zoological Museum in the University of Copenhagen.

Dr. Lund inspected as many as 800 of the Brazilian *lapas*, or bone-caves, of which he had discovered 1600. Of these only sixty yielded any very interesting results, while scarcely half that number contained a sufficient quantity of bones to demand any very prolonged investigation. In some instances, on the other hand, the mass of broken bones was so enormous that from the earth collected in a packing-case whose dimensions did not exceed half a cubic foot, he extracted 400 half jaw-bones of a marsupial and 2000 belonging to different rodents, besides the remains of innumerable bats and small birds. This discovery led to further research, and, after fifteen weeks' continued exploration, he found that one cave, which he had at first estimated to be about 25 feet deep, had a depth of nearly 70 feet, and was so densely packed with bones that the yield of 6500 barrels, of the size of an ordinary butter-firkin, justified the assumption that this special *lapa* contained the remains of seven and a half millions of animals, belonging for the most part to Cavia, Hystrix, and small rodents and marsupials, the estimate being based on the numbers of half jaw-bones extracted from the mould.

In these enormous cave deposits we have, according to Dr. Lund, and his biographer Dr. Reinhardt, a prehistoric ornithological *kökken mödding*, birds of prey having resorted to the *lapas* of Brazil as suitable retreats in which to devour their innumerable victims, whose fractured bones, belonging in almost equal proportions to extinct and living animals, have revealed to us many long-hidden secrets in the history of the changes which the Brazilian fauna has experienced in the course of ages. Comparatively few remains of the larger living mammals have been found, three caves only having yielded evidence of the presence of bears, of which, moreover, the bones of only five individuals were recovered. But while various groups, as *e.g.* the Ungulata, were sparsely represented, several families among the Edentata have contributed so largely to the bone remains of the Brazilian *lapas* that this order would appear to have constituted the most important section of the local fauna, both in past and recent times. Among the cave armadillos, Lund recognized several forms, differing only by their larger size from *Dasypus punctatus*, and *D. sulcatus*; but besides these he found one of colossal dimensions, which, with a body of the size of an ox, and a tail 5 feet in length, exhibited differences of dentition which induced him to assign it to a special genus, to which he gave the name Chlamydotherium. A peculiar characteristic of this fossil animal, whose food he believes was leaves, and not insects, was the fusion or overlapping of several of the vertebræ into nodes, or tangles. In this respect it resembles the still more remarkable armadillo, of whose scales and bones he found enormous quantities, and which he described under the name of Hoplophorus. This animal, of which the different species varied from the size of a hog to that of a rhinoceros, was described about the same time by Prof. Owen, to whom various specimens of its bones had been sent from La Plata, and who established a new species for its reception, to which he gave the name of Glyptodon. The extraordinary rigidity of the shields of some of the Brazilian armadillos, the apparent immobility of the head, and the interlocking of the vertebral bones, make it difficult to understand how these unwieldy animals could have obtained their food. The most probable solution of the problem seems to be supplied by a study of the short massive hind legs, which, with their sharp and powerful claws,

may have served to grub up roots and tubers, and tear off the branches of trailing plants. There is no evidence that our living tardigrades had appeared among the cave fauna of Brazil, where their place was supplied by gigantic gravigrades, resembling the Megatherium.

The results yielded by a careful study of the enormous and varied materials obtained by Dr. Lund in his explorations would appear, generally, to indicate that in post-Pliocene ages the Mammalian fauna of Brazil was richer than in recent times, entire families and sub-orders having become extinct in the intervening ages, or at all events greatly reduced as to the numbers of their genera and species. This is more especially the case in regard to the Edentata, Ungulata, Pachydermata, and Carnivora, which still continue to be characteristic representatives of the South American fauna. In two cases only there is evidence that species which are now exclusively limited to the Old World once inhabited the American continent. A far more marked difference between extinct and living animals is to be observed in the western than in the eastern hemisphere. Thus while the existing Brazilian fauna comprises very few large animals, the predominant forms being almost dwarf-like when compared with their Eastern analogues, the post-Pliocene Brazilian Mastodons, Macrauchenians, Toxodons, and gigantic armadillos and tardigrades, may rank in size with the elephant, rhinoceros, and hippopotamus, which were their contemporaries in Europe at that period of the world's history.

There is no ground for assuming that the change in the South American fauna was due to any natural cataclysm, and it would rather seem to be the result of some regular and slow geological changes, which, by affecting the then existing climatic relations, may have disturbed the conditions of animal life, and thus brought about the destruction, or deterioration, of the larger mammals, which, according to Owen, succumb where the smaller ones adapt themselves to altered conditions.

It was not till near the close of his explorations that Dr. Lund succeeded in finding human bones in such association with fossil remains as to justify the conclusion that man had been the contemporary in Brazil of animals long since extinct in South America. Only seven of the 800 *lapas* examined by him contained any human bones, and in several instances these were either not associated directly with fossil bones, or there were grounds for suspecting that they might have been carried into the caves in comparatively recent ages with the streams that traverse them. In one of these, however, the Sumidouro Lapa, remains of as many as thirty individuals of all ages were found so intermingled with the bones of the gigantic cave jaguar, *Felis protopanther*, and the monster Cavia, *Hydrochœrus sulcidens*, together with several extinct ungulates, that whatever may have been the reason of their presence, there seems to be no ground for doubting that primæval man was contemporaneous with these animals.

The crania, of which admirably drawn illustrations are given, are of a dolichocephalic type, characterized by strongly-marked prognathism, and remarkable for the excessive thickness of the cranial walls. The first communication by Lund of his discovery of human remains in the Lapa di Lagoa do Sumidouro was made (in 1840) in a letter addressed to Prof. Rafn, in which his fear of being accused of recklessness in attaching too high an antiquity to man in Brazil is shown by the pains he takes to indicate every possible means by which these bones might have found their way into the cave. Thus it remained for his annotator, the late Dr. Reinhardt, whose descriptive history of the caves and their exploration has added largely to the interest of the volume before us, to be the first to accept without reservation the co-existence of man with extinct animals which, according to Lund himself, occupied parts of South America more than 5000 years ago.

The monograph treating of the human remains found by Lund is from the pen of Dr. Lütken, the editor of the present work, who also supplies a *résumé* in French of the treatises contributed by his colleagues, Drs. O. Winge and H. Winge, the former of whom writes on the birds of the Brazilian *lapas*, and the latter on the living and extinct rodents of the Minas Geraes district. Besides these important contributions to the work, the reader is indebted to the late Dr. Reinhardt for a detailed description of the situation and geological character of the Brazilian bone-caves, and for an interesting biographical notice of Dr. Lund.

We learn from the preface that this collection of monographs owes, if not its publication, at any rate the complete and elegant form in which it has been produced, to the liberality of the directors of the Carlsberg Trust, at whose cost, with the sanction of the Danish Royal Society, it now forms one of those *éditions de luxe* which have of late years so largely enriched the scientific literature of Denmark. The objection that may be advanced against this, as well as others of the series, is that the writers appear to be moved by an uncalled-for impulse to write down to the level of the general reader, and to explain the origin and progress of each special branch of natural history they are concerned with. Such efforts to popularize the subject lead only to an inconvenient addition to the bulk of the volumes, and are wholly at variance with the scientific aim and object of such publications.

HYDRAULIC MOTORS.

Hydraulic Motors: Turbines and Pressure Engines. By G. R. Bodmer, A.M.I.C.E. "The Specialist's Series." (London: Whittaker and Co., 1889.)

THE essential detail which lifts the mere water-wheel to the rank of a turbine consists, according to the author, in some arrangement for directing the water over the buckets in the most advantageous manner, instead of allowing the water merely to follow its own course. Again, in a water-wheel only a small part of the wheel is really at work at a time, the buckets of the remaining part being empty; while a turbine is arranged, as a rule, with a vertical axis, and all parts of the wheel are simultaneously taking their fair share of the work. In this respect there is a great resemblance and analogy to the distinction between the two chief instruments of ship propulsion by steam—the paddle-wheel and the screw propeller. In the paddle-wheel only a few of the floats act on the water at a time; while in the screw propeller, completely submerged, all parts are equally at work, implying a great saving of weight in the propelling instrument. Mr.

Thornycroft, with his turbine propeller, is able to emphasize this economy of weight still further, and, but for difficulties of going astern not yet surmounted, would be able to save considerable weight and space in sea-going steamers with this contrivance.

As regards their construction, turbines are divided into three classes (p. 24)—the radial, axial, and mixed-flow—according to the mode in which the water enters and passes through the turbine; but as regards the dynamical principle on which the turbines work, they are divided into two classes (p. 25), the *reaction* and the *impulse* turbine.

In the reaction or Jonval turbine, described in chapters iii. to vi., the passages are completely filled with water, and the changes of pressure play an important part in the work performed. This turbine possesses the advantage of being able to work when drowned by the tail race, or when elevated above the tail water to a height anything less than the height of the water barometer, a suction tube of properly adjusted shape being fitted below the turbine to carry off the water at pressure gradually increasing downwards to the atmospheric pressure. Against this are the disadvantages of imperfect regulation for varying load, and that with a high fall this turbine must be made so small and must run so fast as rapidly to wear out, as in the Fourneyron turbines at St. Blaise (p. 422); but this disadvantage the author professes (p. 263) to avoid by compounding the turbine, just as we compound the steam-engine with high-pressure steam.

The impulse or Girard turbine, on the other hand (chapters vii. and viii.), derives its power entirely from the change of momentum of the water without change of pressure; the buckets are freely ventilated, and consequently this turbine can only work in communication with the surrounding air. It possesses, too, the great advantage of complete regulation of power by merely altering the supply of water. Girard turbines are divided into outward flow (Fourneyron) turbines, and inward flow (James Thomson); the latter, although more weighty and costly, possessing the advantage of greater stability of motion.

In their difference of action we may compare the Jonval turbine with the screw propeller, which works entirely immersed, and derives its reaction partly from the change of pressure in the water; while the Girard turbine resembles the paddle-wheel in working at the surface of separation of the water and air, so that no appreciable change of pressure is manifest. Against this analogy, however, we find the screw propeller far less susceptible to changes of immersion than the paddle-wheel, whence the manifest superiority of the screw for long voyages.

In chapters ix. to xi. the author gives a very valuable collection of numerical applications of his theories to actual turbines on a large scale. In designing a turbine to utilize a fall, the first important measurement is that of the quantity of the stream of water; the speed of the turbine is next determined from the consideration that the best theoretical speed is half (or a little more than half) the speed at which the turbine would run if unloaded; and then various practical considerations intervene in deciding whether the turbine should be reaction or impulse, outward, inward, or mixed flow.

At Holyoke, Mass., the Water-Power Company, under Mr. James B. Francis, controlling the falls of the Connecticut, undertake the commercial testing of turbines submitted to them, and have checked to some extent the wild claims of efficiency, reaching and even exceeding 100 per cent., which American turbine makers are said to have claimed in their advertisements. There is still, however, an efficiency claimed for American turbines which has not been rivalled in Europe: this cannot be attributed to defect in our designs, and the author thinks must be attributed to the less care bestowed in America on the measurement of the quantity of water consumed. It is noticeable that the American turbines are generally of the reaction Jonval type, which is more suitable for their unlimited supplies of water by reason of its smaller weight and cost; here in Europe, where water is scarcer, the impulse Girard turbine is more in favour.

For mining purposes, especially in California, with great falls of 400 or 500 feet and small quantities of water, the hurdy-gurdy or Pelton wheel (p. 419) is a favourite, and in a paper by Mr. Hamilton Smith, Jun., of the American Society of Civil Engineers, the efficiency of this wheel and its practical advantages are declared to be very high. Similar small impulse turbines seem likely to come into general domestic use.

The author concludes (chapter xiii.) with a description of the various hydraulic pressure engines and motors of Armstrong, Rigg, and others. These engines act by pressure only, like the steam-engine, with the disadvantage of using the same quantity of water whether working at high or low power, except in the case of Mr. Rigg's motor. Such motors are, however, coming into great use on ships, not only for working the guns, but for steering, loading, and discharging cargo.

Although designed, and amply fulfilling its purpose, as a practical treatise on hydraulic motors, this book will provide the pure theorist with some of the most elegant applications of relative velocity, aberration, dynamical principles, and of hydromechanics; and it is instructive to notice that, as in all practical mechanical treatises, gravitation units of force only are employed, even in the hydrodynamical equations of Borda and Carnot, or of Bernoulli, as we think they should be called. All this is in direct opposition to the theoretical text-books; theorist or practical man, which is to give way?

A. G. G.

PHYSIOLOGY OF EDUCATION.

Physiological Notes on Primary Education and the Study of Language. By Mary Putnam Jacobi, M.D. (New York and London: G. P. Putnam's Sons, 1889.)

THIS is a remarkable book. The authoress is an original thinker who knows how to express her thoughts clearly and strongly. It is worthy of being read by all interested in the science of education, though few perhaps even of the advocates of the present educational renaissance would be prepared to receive every one of her conclusions.

The work consists of four distinct essays. The first two are entitled "An Experiment in Primary Education," and describe the way in which Dr. Mary Jacobi taught

her own little girl. She commences the account with some very valuable remarks on the right order of studies.

"The first intellectual faculties to be trained are perception and memory. The subjects of the child's first studies should therefore be selected, not on account of their ultimate utility, but on account of their influence upon the development of these faculties. What sense is there then in beginning education with instruction in the arts of reading and writing? . . . From the modern standpoint, that education means such an unfolding of the faculties as shall put the mind into the widest and most effective relation with the entire world of things—spiritual and material,—there is an exquisite absurdity in the time-honoured method. To study words before things tends to impress the mind with a fatal belief in their superior importance."

As forms and colours are the elements of all visual impressions, Dr. Jacobi began to teach her child geometrical forms before she was four years of age. At four and a half the little girl began elementary colours. Afterwards she made acquaintance with the points of the compass, the main ideas of perspective, and then maps and geography. The study of number, of course by concrete illustrations, followed that of form and outline The observation of natural objects, especially that of plants and plant-life, was then commenced. The growth of beans and hyacinths was carefully watched, and the daily observations made by the child were written down by the mother, till she attempted them herself, and became gradually initiated into the mysteries of writing. This led her on easily to the art of reading when she was about six years of age. The progress of the child's mental development during these early years is fully described, with many pleasant recollections of her sayings.

The third part consists merely of a criticism of Miss Youman's views on the teaching of botany, and an argument in favour of commencing in a child's education with the flower rather than the leaf.

Half the book, however, is occupied by the fourth essay, in which the authoress treats of "The Place for the Study of Language in a Curriculum of Education." Of course she places it after the mind has been trained to deal with sense perceptions of external objects; but she contends earnestly for the importance of the study of words, especially for the power it possesses of enabling the child to form abstract conceptions. The authoress enters largely into the brain action involved in the use of verbal signs or complex ideas, and illustrates her views of the matter by means of physiological diagrams. She also describes a little device for the comparison of verbal roots, which she terms "language tetrahedrons," and which are intended to show the relation between Latin, French, German, and English. She would devote to literary studies, including English, the best part of the time between the Kindergarten training and the age of fourteen.

"To the study of words may be brought the scientific methods used in the study of things—observation, analysis, comparison, classification; and the child may thus begin to be trained for physical science at a time when the pursuit of most physical sciences is impossible."

It may be that Dr. Mary Jacobi claims too much time for the study of language, but the old-fashioned educationalists will get little consolation from her concessions; for she not only places the study of words after that of things, but she would have several forms of Aryan speech studied simultaneously, and she would postpone the study of grammar till two years after the serious study of language has commenced. She believes that the power of abstraction and the general mental training gained by these philological studies will enable the young person at an early age to enter upon more serious matters of study or those of more immediate practical utility.

J. H. G.

OUR BOOK SHELF.

Steam-Engine Design. By Jay M. Whitham, Professor of Engineering, Arkansas Industrial University. (London: Macmillan and Co., 1889.)

In this work the author treats of the application of the principles of mechanics to the design of the parts of a steam-engine of any type or for any duty. He acknowledges that he has culled as much information as he has required from well-known sources, both English and American; and he has embodied, as a sort of foundation for his work, a course of lectures given to his class at the United States Naval Academy by P.A. Engineer John C. Kafer, U.S.N.

After careful study, we can say that the book appears to be well suited for its purpose. The arrangement of information, both principles and details, is much the same as that in Mr. A. E. Seaton's excellent work on marine engineering; but the field covered is of far less extent, and the boiler and its accessories are not included. The author being a Professor of Engineering in an American University, we expected to find some variations from our own practice in steam-engine design. In this, however, we were disappointed. A few of the woodcuts represent parts of engines differing in insignificent details from those used in this country, but the main design is practically the same. It is gratifying to find many of our own engineers quoted as authorities in the volume—viz. D. K. Clark, A. E. Seaton, R. Sennett, and many other well-known English authorities.

It must not be supposed that there is no original work in this book. Chapters ii. and iii. for instance, on the design of slide valves and reversing gears, are ample evidence of hard work on the part of the author: his descriptions and diagrams of the various motions are excellent. Chapter iv. deals with the general design and proportions of the steam-chest, valves with their various connections. Chapters v. and vi. are on compound and triple-expansion engines, and contain also a theoretical treatment of indicator diagrams of a compound engine. These chapters are well written, and contain much useful information, but as a whole they do not teach anything new. To chapters vii. and viii., written by P.A. Engineer Asa M. Mattice, U.S.N., the same remarks will apply. The remaining chapters deal with the design of the various other parts of a steam-engine. The methods used are those well understood in every drawing-office worthy of the name, and they need not be further noticed here.

Taken as a whole, the book deserves praise for good and careful work; and we may especially call attention to the theoretical considerations, which are always clearly expressed. Although published by Messrs. Macmillan, the work is from an American press, that of Messrs. Ferris Bros., New York. The printing and woodcuts are excellent—far better, as usual, than English work of the same class.

N. J. L.

Coloured Analytical Tables. By H. W. Hake, Ph.D., F.I.C., F.C.S. (London: George Phillip and Son, 1889.)

Novelties in text-books of elementary qualitative analysis are usually conspicuous by their absence, but the

book before us takes an entirely new departure. The idea of representing the various coloured reactions by tinted imitations is, so far as we know, quite new. Apart from this, the usual well-worn paths are followed. The tables are of the simplest character, and are only sufficient for the detection of common bases in salts or oxides, no attempt being made to separate the members of the various groups. The second part is devoted to reactions for the detection of a few acids and organic substances.

The book is apparently primarily intended for the use of students preparing for the preliminary examination of the Conjoint Board of the Royal College of Physicians and Surgeons, but it will no doubt have a much wider field of usefulness if it survives the test of experience. The new method of representation seems excellently adapted for young students, and certainly no harm can be done by giving it a fair trial.

The reactions illustrated include precipitates, charcoal reactions, borax beads, and flame colorations, most of which are fairly well represented.

The Story of a Tinder Box. By Charles M. Tidy, M.B.M.S., F.C.S., &c. (London: Society for Promoting Christian Knowledge, 1889.)

POPULAR lecturers have discovered for some time that the history of the methods that have been used for obtaining a light is an excellent subject wherewith to please the public mind, and this book contains the reports of three such lectures delivered to a juvenile auditory last Christmas. An attempt has also been made to describe the experimental portion of the lectures, and the author has not committed the common error of giving a multiplicity of pretty but irrelevant experiments conveying a paucity of information. In fact, in some parts the reverse seems the case, for we must confess our inability to discover why a consideration of the allotropic modifications of carbon should necessitate a detailed description of the manufacture of black lead pencils. This digression, however, does not detract from the interest and general merit of the work, which certainly contains the explanation in simple language of some elementary physical and chemical phenomena.

Magnetism and Electricity. Part I. Magnetism. By Andrew Jamieson, M.I.C.E. (London: Griffin and Co., 1889.)

ALTHOUGH elementary text-books of physics continue to increase in number, there is still room for one of such general excellence as Prof. Jamieson's elementary manual. The book is specially arranged for the use of first year Science and Art Department and other electrical students. Numerous questions and specimen answers are distributed throughout the book, and though this may be rather suggestive of cram, there is nothing in the text to justify such a suggestion. It is unnecessary to go into details, but it may be stated that the arrangement of subjects is as good as it well can be, and on the whole the descriptions are very clear. The numerous diagrams are also excellent, those of the mariner's compass being especially good; indeed, the whole chapter on terrestrial magnetism is the best elementary account of the subject which has come under our notice.

The subject is throughout considered as an essentially practical one, and very clear instructions are given for the making of magnets, and compass and dipping needles.

If the succeeding parts of the book confirm the good opinion created by the first, teachers of the subject are to be congratulated on having such a thoroughly trustworthy text-book at their disposal.

Time and Tide: A Romance of the Moon. By Sir Robert S. Ball, LL.D., F.R.S. (London: Society for Promoting Christian Knowledge, 1889.)

THE ability of the author of this work to give a lucid exposition of an abstruse subject is a matter of common knowledge; and hence the fact that the book contains two of his lectures delivered at the London Institution last November is in itself sufficient commendation. However, be this as it may, we have no hesitation in saying there could hardly be a clearer explanation of Prof. George Darwin's theory of tidal evolution than that contained in the work before us. The hypothesis being accepted, every feature of the past and future condition of our satellite is described in a most comprehensive manner. It is first shown how, when the earth was rotating on its axis with an enormous velocity, the tidal action set up by the sun caused a portion to become detached and form our satellite. The employment of the term "conservation of spin" facilitates considerably the demonstration of the fact that as by tidal action the spin of the earth decreases—as our day lengthens—so must the dimensions of the moon's orbit be increased, and the length of the month therefore become proportionally greater. The application of Prof. Darwin's theory to other members of our system is also inquired into; and although the author does not attempt to go back to the first stage in the evolution of celestial species, he shows that tidal evolution is an extension of the hypothesis that does so. Indeed, the book is replete with information, and by the general scientific reader will be found exceedingly interesting.

Specific Inductive Capacity.

PERHAPS a better mode of performing the experiment quoted by Mr. Rudge (p. 10) is to have two insulated parallel metal plates, one connected with an electroscope, the other with a slightly-charged Leyden-jar. On now interposing a thick slab of paraffin or ebonite (recently passed through a flame) between the plates, a very decided increase of divergence will be perceived. Unless, indeed, the electroscope should happen to have overflowed to earth during the charging of the jar, in which case it will be oppositely charged and a decreased divergence will be caused. To interpose the slab is, in fact, virtually to diminish the distance between the plates, and its effect is therefore the same as that of pushing the plates closer together.

The advantage of the Leyden-jar is that it keeps the potential practically constant. If an isolated plate or sphere is used as the charged body, the circumstances are not so simple, for the insertion of the slab reduces the potential and slightly increases the charge on the near face of the plate, so that, whether the divergence of the leaves is increased or diminished depends on several unimportant considerations, of which the size of the slab may be one. A slab of area comparable to that of the plates between which it is put would in this case be the most suitable; and in any case it should be supported by a long insulator, so that the operator's arm, as it approaches, shall not complicate and mask the effect. "La Pietra Papale."

ABOVE Stresa, on the western bank of Lago Maggiore, there is an enormous granite boulder, which deserves the attention of geologists. It lies on the left slope of an old moraine, near the little village of Gignese, and not far from the Hotel Alpino, at an elevation of about 2500 feet above the sea-level. It is roughly oblong in shape, and measures some 75 feet in length, and perhaps half as much in breadth and thickness. The projected mountain railway from Stresa to the summit of Monte Motterone will pass close to the spot where it lies, and the masons are already engaged in converting the smaller boulders into building-stones. It is to be hoped, however, that *la pietra papale*, as this splendid example of the carrying powers of ice is

called by the villagers, will not suffer the like fate. The Italian Alpine Club, will, we may trust, interest themselves in this matter. P. L. SCLATER.

Who discovered the Teeth in Ornithorhynchus?

As Dr. Hart Merriam's letter on the above subject in your issue of the 7th inst. (p. 11) will be read by many who have not access to Sir Everard Home's "Lectures on Comparative Anatomy," allow me to point out that the description and figures in that work referred to by Dr. Merriam have no bearing whatever upon the very interesting discoveries recently made. They represent, not the real teeth of the young animal discovered by Mr. Poulton, and fully described by Mr. Oldfield Thomas, but the well-known horny plates which functionally take their place in the adult, and which are called "grinding teeth" by Sir Everard only in a very general sense. W. H. FLOWER.

British Museum (Natural History), November 9.

THE account of the teeth of Ornithorhynchus, given by Sir Everard Home in "Lectures on Comparative Anatomy," vol. i. p. 305, explanatory of Tab. lix. vol. ii., referred to by Mr. Hart Merriam in your last issue (p. 11), shows, even more clearly than the figures, that the *true* teeth had not been noticed at that time (1814). The passage is as follows:—"In the posterior portion of the mouth, both in the upper and lower jaw, are placed grinding teeth with broad flattened crowns, four in number, one on each side of each jaw. *They are composed of a horny substance* (the italics are my own), only embedded in the gum, to which they are connected by an irregular surface in the place of fangs. When cut through, the substance appears fibrous, like that of nail; the direction of the fibres being perpendicular to the crown, similar to that of the horny crust of the gizzard. The teeth in the young animal are smaller, and two on each side, so that the first teeth are probably shed, and the two small ones replaced by one large one."

It is perfectly evident that here no reference is made to the *true* teeth, and, moreover, the figure of the two smaller "teeth" of young specimens represents merely the immature horny plates. The honours, therefore, still remain with Mr. Poulton and Mr. Oldfield Thomas. OSWALD H. LATTER.

On a Mite of the Genus *Tetranychus* found infesting Lime-trees in the Leicester Museum Grounds.

ABOUT the 13th of last September my attention was called to the strange appearance of a row of lime-trees standing in front of the School of Art buildings in Hastings Street. On examination I found that the whole row, with, I think, only one exception, were almost entirely devoid of leaves, the trunks and branches being covered with a fine web, very closely spun, giving them the appearance of being coated with a thin layer of ice, this glazed look being specially noticeable when standing in such a position as to catch the reflected rays of the sun. At first sight I imagined that I was examining the work of a spider, though I was unable to recollect any whose webs would accord with the character of those under observation. However, a close inspection revealed the webs to be tenanted by an innumerable number of yellowish or orange-coloured mites which were in some places associated together in dense masses or clusters, and more or less abundant over the whole of the trunks and branches.

These mites appeared, on being subjected to a careful microscopical examination, to be identical with *Tetranychus tiliarum*, Mull., a species which it seems that Claparède considers to be only a variety of *T. telarius*, the common "red spider." However that may be, they are at any rate closely allied forms—members of the family *Trombidiidæ*, which possess, as one of their distinguishing characteristics, a pedipalpus with a claw and a lobe-like appendage. In the genus *Tetranychus* the palpi are chelate, the mouth is furnished with a barbed sucking apparatus for the extraction of plant juices, and spinning organs are usually present. It is needless to comment upon their destructiveness to vegetation, for most keepers of gardens and hothouses are familiar with their ravages in one direction or another, and the difficulty experienced in thoroughly extirpating them.

In connection with the species which forms the subject of the present communication, I notice that Murray, in his work on the "Aptera," says: "It occasionally occurs in such numbers as almost to denude the trees of their foliage; and it has been noted that the stems and branches of such trees seemed covered with a bright glaze. Can this be a fine web?" It was so, most certainly, in the present instance, which afforded me a most favourable opportunity for examination. Again, it appears that the mites are normally found on the under-surface of the leaves, which they cover with a fine web of silk, on which (to again quote Murray) "they are sometimes crowded together in vast numbers; for example, we have seen them so thick on the leaves that they looked as if they were not merely sprinkled with a yellow orange-coloured powder, but as if it was actually in parts heaped up on them, so that none of the green colour of the leaf was visible." Their presence is of course highly injurious, causing the leaves to shrivel and drop; and it seems to me that the fact of their occurrence on the bare bark of the trunks was attributable to the death of the leaves causing them to retreat to that position, uncongenial though it would seem to be. Such trees as preserved their foliage presented no abnormal appearance on the branches, &c., notwithstanding which, in one or two instances, I believe the parasites were present on the leaves, though seemingly not in such extraordinary profusion.

Dugès, writing of *T. telarius*, states his belief that that species passes the winter under stones, and instances the finding of several active individuals so situated in a garden near Paris in the month of October. Regarding this point I may say that my specimens of *T. tiliarum*, which I placed in a box immediately after removal from the trees, speedily ensconced themselves in the most convenient nooks and crannies, in which they spun fine webs. It may be worth noting that the days on which my observations were made were warm and damp, with scarcely any wind, quite typical early autumn days in fact.

Retarded Germination.

I SHALL be much obliged to any of your readers who can give an explanation of the probable cause of the above phenomenon, which I have remarked this year. I sowed a number of patches of seeds of various hardy annuals in the garden in the last week of April; about half of them came up after the usual interval, strongly and regularly. Such were *Calendula Pongei*, *Convolvulus minor*, *Lavatera trimestris*, *Collinsia bicolor*, *Iberis* white and red, *Specularia speculum*, *Linum rubrum*, &c., &c. Then there were some of which a few scattered seedlings made their appearance at this time, and after an interval of about six weeks the greater part of them also came up; among these were *Eutoca viscida*, *Nigella damascena*, *Sphenogyne*, and *Clarkia pulchella*. Thirdly, there were some of which I quite despaired; mignonette, however, appeared thinly about the end of June, and at intervals till August; and in the middle of June a few plants (in proportion to the seed sown, a few) of *Linaria bipartita*, *Madia elegans*, and *Xeranthemum* came up—one consequence being that the last named has not yet flowered. Some of the seeds were obtained this spring from seedsmen, some were my own collection of the last year or two—of the latter were *Calendula*, *Lavatera*, *Convolvulus*, *Specularia*, *Eutoca*, *Nigella*, *Sphenogyne*, and mignonette—so that cannot be said to give any clue. The conditions for germination and growth were favourable, and the season also. I have never remarked before any *annuals* so long in appearing above ground; though in some herbaceous plants I have noticed it, *e.g.* *Gaillardia*, *Myosotis alpestris*, and *Anemone coronaria*. Herefordshire, September 19.

The Relation of the Soil to Tropical Diseases.

As a humble subscriber to and student of NATURE, will you bear with me while I ask your help, as shortly and plainly as I can? I am in a very secluded corner of one of the Native States of Rajpootana, and I am collecting facts and making observations on the relation of the *soil* to tropical diseases; my ambition being to discuss it not so much from a statistical and geographical standpoint, as from the geological, in its chemical and biological

aspects; though, as I conceive, the geographical, climatological, and geological elements in the problem are not to be arbitrarily distinguished. Now I am far away from all books of reference, and it is of course essential that I make myself acquainted with what has already been done in these subjects, and I venture to ask for any hints as to the bibliography of them. Can you tell me if anyone has done for geology what Hirsch, of Berlin, has done for geography (in his work on the distribution of disease)? Is there any authority on the chemistry of soils, and what I roughly call their physiology and pathology, their structural and functional changes under influences—climate notably—and their own intrinsic, and the deeper geological interactions?

The Earthquake of Tokio, April 18, 1889.

DR. VON REBEUR-PASCHWITZ'S letter, which appeared in NATURE, vol. xl. p. 294, is of special interest to us in Japan, countenancing as it does the conjecture that the very peculiar earthquake felt and registered here on April 18 was the result of a disturbance of unusual magnitude. It was my good fortune on the day in question to be engaged in conversation with Prof. Sekiya in the Seismological Laboratory at the very instant the earthquake occurred. We at once rushed to the room where the self-recording instruments lay, and there, for the first time in our experience, had the delight of viewing the pointers mark their sinuous curves on the revolving plates and cylinders. At first sight it seemed as if the pointers had gone mad, tracing out sinuosities of amplitudes five or six times greater than the greatest that had ever before been recorded in Tokio. There was not much *sensation* of an earthquake; indeed, after the first slight tremor that attracted our attention, we felt nothing at all, although in the irregular oscillations of the seismograph pointers we had evidence enough that an earthquake was passing. Very few in Tokio were aware that there had been an earthquake till they read the report of it in the next day's papers. Thus the motion, though large, was too slow to cause any of the usual sensations that accompany earthquakes, and suggested a distant origin and a large disturbance, with a consequent wide extension of seismic effect. Excepting the slight tremors recorded at Potsdam and Wilhelmshaven, there has been, so far, no evidence of any such far-reaching action.

My object in writing this note, however, is to correct an error of calculation which Dr. von Rebeur-Paschwitz has unwittingly made. He has assumed that Tokio standard time is mean local time. On the contrary, the standard time for all Japan is the mean solar time for longitude 135° E.,—that is, nine hours in advance of Greenwich mean time. Hence, instead of the Tokio earthquake having preceded the German disturbance by 1h. 4·3m. it preceded it by only 45m. This correction increases the velocity of transmission to 3060 metres per second. We must assume, then, either that large disturbances in the heart of the earth travel with exceptionally high speeds, or that the origin of the disturbance was a considerable distance from Tokio. The latter assumption seems sufficiently satisfactory, if in other respects Dr. von Rebeur-Paschwitz's views meet with approval.

A Brilliant Meteor.

YESTERDAY evening, November 4, at 7.55 p.m., I was fortunate enough to observe a very brilliant meteor. It became visible almost exactly at the zenith, or a little west of it, and moved, as nearly as I could judge, due east, magnetic; it remained visible for about from one to two seconds, disappearing, finally, rather low down on the eastern horizon. For the first half of its journey it was of a dazzling white brightness, and then it suddenly became a dull red spark. The light emitted from it when brightest reminded me of the light from an arc lamp, and was very much brighter than any of the fixed stars.

As it was so short a time in view, and there were no stars visible, I could only approximately estimate its point of appearance and path. There were a few clouds about, mostly in the west, and the moon was behind them. PAUL A. COBBOLD.

Warwick School, November 5.

ON THE HARDENING AND TEMPERING OF STEEL.[1]

II.

THE following considerations appear to have guided Osmond in beginning his investigations (see *ante*, p. 16). Bearing in mind the fact that molecular change in a body is always accompanied by evolution or absorption of heat, which is, indeed, the surest indication of the occurrence of molecular change, he studied with the aid of a chronograph what takes place during the slow cooling and the slow heating of masses of iron or steel, using, as a thermometer to measure the temperature of the mass, a thermo-electric couple of platinum and of platinum containing 10 per cent. of rhodium, converting the indications of the galvanometer into temperatures by Tait's formulæ.

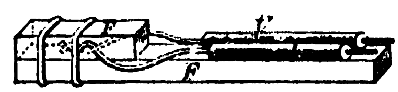

FIG. 5.

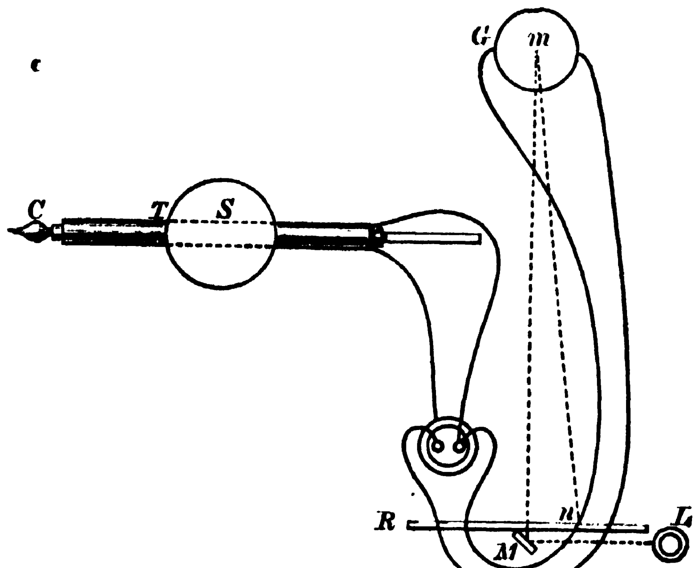

FIG. 6.

FIGS. 5 and 6 show the actual mode of conducting the experiments. F (Fig. 5) is a piece of steel into which a platinum and platinum-rhodium couple, *t*, *t'*, is fixed. It is inclosed in a glazed porcelain tube and heated to bright redness in the furnace, S (Fig. 6). This tube, T, may be filled with any gaseous atmosphere. C is a bulb filled with chloride of calcium. The metal under examination is slowly cooled down. The wires from the thermo-couple pass to the galvanometer, G. The rate of cooling of the mass is indicated by the movement of a spot of light from the galvanometer mirror at *m*, on the screen, R, and is recorded by a chronograph. The source of light is shown at L; M is a reflector.

In the next diagram (Fig. 7) temperatures through which a slowly-cooling mass of iron or steel passes, are arranged along the horizontal line, and the intervals of time during which the mass falls through a definite number (6·6) of degrees of temperature are shown vertically by ordinates. See what happens while a mass of electro-deposited iron (shown by a dotted line), which is as pure as any iron can be, slowly cools down. From 2000° to 870° it falls uniformly at the rate of about 2·2° a second, and the intervals of temperature are plotted as dots at the middle of the successive points of the intervals. When the temperature falls down to 858°, there is a sudden arrest in the fall of temperature, the indicating spot of light, instead of falling at a uniform rate of about 2° a second, suddenly takes 26

[1] A Lecture delivered on September 13, by Prof. W. C. Roberts-Austen, F.R.S., before the members of the British Association. Continued from p. 16.

seconds to fall through an interval of temperature which hitherto and subsequently only occupies about 6 seconds. Turn to the diagram, and see what actually happens when the iron contains carbon in the proportion required to constitute it mild steel (shown by thin continuous line, Fig. 7); there is not one, but there are two such breaks in the cooling, and both breaks occur at a different temperature from that at which the break in pure iron occurred. As the proportion of carbon increases in steel, the first break in cooling travels more and more to the right, and gradually becomes confounded with the second break, which, in steel containing much carbon, is of long duration, lasting as much as 76 seconds in the case of steel containing 1·25 per cent. of carbon (thick continuous line, (Fig. 7).

[In the experiments shown to the audience the spot of light moved slowly and uniformly along a screen ten feet in length. It halted for a few seconds as the temperature of the cooling mass of steel fell to about 850° C., and when the metal was at dull redness, the spot of light remained stationary for 68 seconds, and then resumed its course.]

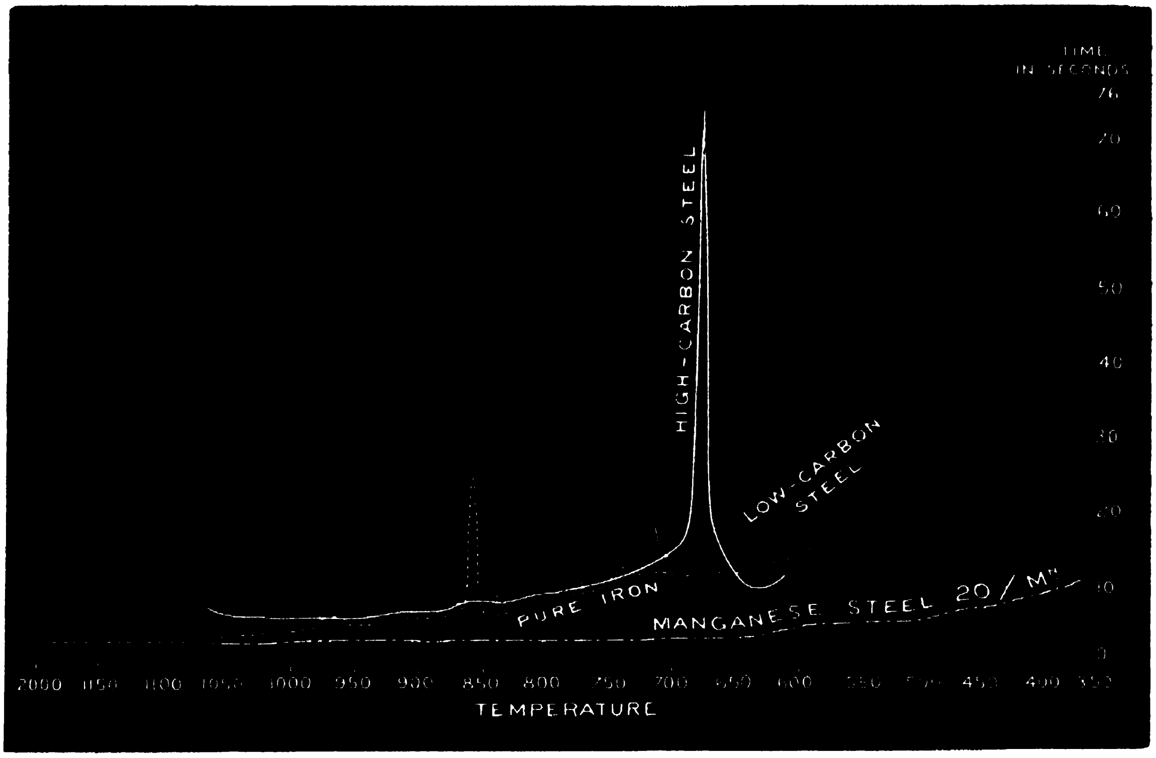

FIG. 7.—The curves in this diagram show how the rate of movement of the spot of light varies with different samples of steel. The stoppage of the movement of the spot of light of course indicates the evolution of heat from the cooling mass of steel, F (Fig. 5).

Now, it may be urged, evidently the presence of carbon has an influence on the cooling of steel when left to itself: may it not affect molecular behaviour during the rapid cooling which is essential to the operation of hardening? We know that the carbon, during rapid cooling, passes from the state in which it is combined with the iron into a state in which it is dissolved in the iron; we also know that, during slow cooling, this dissolved carbon can re-enter into combination with the iron so as to assume the form in which it occurs in soft steel. Osmond claims that this second arrestation in the fall of the thermometer corresponds to the recalescence of Barrett, and is caused by the re-heating of the wire by the heat evolved when carbon leaves its state of solution and truly combines with the iron.

If it is hoped to *harden* steel, it must be rapidly cooled before the temperature has fallen to a definite point, not lower than 650°, or the presence of carbon will be unavailing. But what does the first break in the curves mean? You will see that a break occurs in electrotype iron which is free from carbon (thin dotted line, Fig. 7); it must then indicate some molecular change in iron itself, accompanied with evolution of heat—a change with which carbon has nothing whatever to do, for no carbon is present; and Osmond argues thus:—There are two kinds of *iron*, the atoms of which are respectively arranged in the molecules so as to constitute *hard* and *soft iron*, quite apart from the presence or absence of carbon. In red-hot iron the mass may be soft but the molecules are hard—let us call this β iron; cool such red-hot pure iron, whether quickly or slowly, and it becomes soft; it passes to the α soft modification—there is nothing to prevent its doing so. It appears, however, that if carbon is present, and the metal be rapidly cooled, the following result is obtained: a certain proportion of the molecules are retained in the form in which they existed at a high temperature—the hard form, the β modification—and hard *steel* is the result.

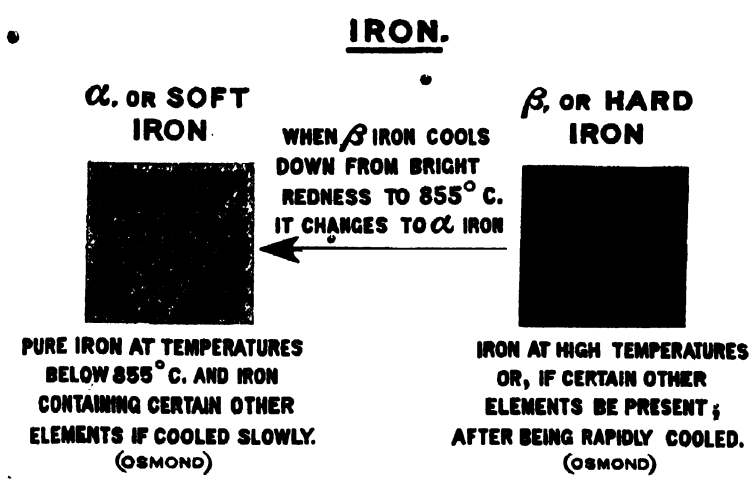

FIG. 8.

The main facts of the case may, perhaps, be made clearer by the aid of this diagram (Fig. 8) which shows the relation between α and β iron. This molecular change from β iron to α iron during the slow cooling of a mass of iron or steel is, according to Osmond's theory, indicated by the first break in the curve, representing the slow cooling of iron, as is proved by the fact that it occurs alone in electro-iron. A second break, usually one of much longer duration, marks the point at which carbon itself changes from

the dissolved or hardening carbon to the combined carbide-carbon. It follows that, if steel be quickly cooled *after the change from β to α* has taken place but before the carbon has altered its state—that is, before the change indicated by the second break in the curve has been reached—then the iron should be soft, but the carbon, hardening carbon; and as such, the action of a solvent should show that it cannot be released from iron in the black carbide form. This proves to be the case, and affords strong incidental proof of the correctness of the view that two modifications of iron can exist.

It will be seen, therefore, that, although the presence of carbon is essential to the hardening of steel, the change in the mode of existence of the carbon is less important than has hitherto been supposed.

The α modification of iron may be converted into the β form by stress applied to the metal at temperatures below a dull red heat, provided the stress produces permanent deformation of the iron,[1] but the consideration of this question would demand a lecture to itself. I am anxious to show you an experiment which will help to illustrate the existence of molecular change in iron.

Here is a long bar of steel containing much carbon. In such a variety of steel, the molecular change of the iron itself, and the change in the relations between the carbon and the iron, would occur at nearly the same moment. It is now being heated to redness, but if you will look at this diagram (Fig. 9), you will be prepared for what I want

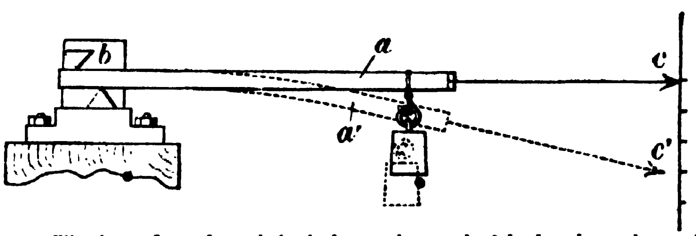

FIG. 9.—The bar of steel, *a*, ½ inch in section and 18 inches long, heated to bright-redness and firmly fixed in a vice or other support at *b*. A weight of about 2 pounds is rapidly hung on to the free end, and a light pointer, *c*, is added to magnify the motion of the bar. It remains perfectly rigid for a period varying from 30 to 40 seconds, and then, when the bar has cooled down to very dull redness, it suddenly bends, the pointer falling from 6 to 8 inches to the position *c'*.

you to see in the actual experiment. One end of the red-hot bar *a* will be firmly fixed at *b*, a weight *not sufficient to bend it* is slung to the free end, which is lengthened by the addition of a reed, *c*, to magnify any motion that may take place. Now remember that as the bar will be red-hot it ought to be at its softest, you would think, when it is freshly withdrawn from the furnace, and if the weight was ever to have power to bend it, it would be then; but, in spite of the rapidity with which such a thin bar cools down in the air and becomes rigid, points of molecular weakness come when the iron changes from β to α, and the carbon passes from hardening carbon to carbide-carbon; at that moment, at a temperature much below that at which it is withdrawn from the furnace, the bar will begin to bend, as is shown by the dotted lines *a'*, *c'*. It has been found experimentally that this bend occurs at the point at which, according to Osmond's theory, molecular change takes place. Mr. Coffin takes advantage of this fact to straighten distorted steel axles.[2]

There is a sentence in the address which has just been delivered before Section G, by Mr. Anderson, which has direct reference to molecular change in iron. He says:—

"When, by the agency of heat, molecular motion is raised to a pitch at which incipient fluidity is obtained, the particles of two pieces brought into contact will interpenetrate or diffuse into each other, the two pieces will unite into a homogeneous whole, and we can thus grasp the full meaning of the operation known as 'welding.'"

It is, however, possible to obtain evidence of interchange of molecular motion, as has been so abundantly shown by Spring, even at the ordinary temperature, while, in the case of steel, it must take place far below incipient fluidity—indeed, at a comparatively low temperature, as is shown by the following experiment on the welding of steel. Every smith knows how difficult it is to weld highly carburized hard tool-steel, but if the ends of a newly-fractured $\frac{3}{16}$-inch square steel rod, *a* (Fig. 10), are placed

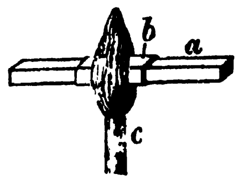

FIG. 10.

together and covered with platinum foil, *b*, so as to exclude the air, and if the junction is heated in the flame of a Bunsen burner, *c*, the metal will weld, without pressure, so firmly that it is difficult to break it with the fingers, although the steel has not attained a red-heat.[1]

The question now arises, What is the effect of the presence of other metals in steel, of which much has been heard recently? (1) Manganese. Osmond has shown that this metal enables steel to harden very energetically, as is well known. If much of it be present, 12 to 20 per cent., in iron, *no break whatever* is observed in the curve which represents slow cooling (see line marked "manganese steel" (Fig. 7). That is, the iron never shows such a change as that which occurs in other cooling masses of iron. Then you will say such a material should be hard however it is cooled. So it is. There is one other important point of evidence as to molecular change connected with the addition of manganese to submit to you. Red-hot iron is not magnetic. Hopkinson[2] has shown that the temperature of recalescence is that at which iron ceases to be magnetic. It may be urged that β iron cannot therefore be magnetized. Steel containing much manganese cannot be magnetized, and it is therefore fair to assume that the iron present is in the β form. Hadfield[3] has given metallurgists wonderful alloys of iron and manganese in proportions varying from 7 to 20 per cent. of manganese. This core of iron round which a current is passing, attracts the sphere of iron, but if nothing is changed, except by replacing the core of iron with a core of Hadfield's steel, it is impossible to make a magnet of it. [Experiment shown.]

Prof. Ewing, who has specially worked on this subject, concludes that, "no magnetizing force to which the metal is likely to be subjected in any of its practical applications would produce more than the most infinitesimal degree of magnetization" in this material.

It has been seen that quantities of manganese above 7 per cent. appear to prevent the passage of β iron into the α form. In smaller quantities manganese seems merely to retard the conversion, and to bring the two loops of the diagram nearer together.

Time will not permit me to deal with the effect of other elements on steel. I will only add that tungsten possesses the same property as manganese, but in a more marked degree. Chromium has exactly the reverse effect, as it enables the change of hard β iron to α soft iron to take place at a higher temperature than would otherwise be the case, and this may explain the extreme hardness of chromium steels when hardened in the same way as ordinary steels.

There are a few considerations relative to the actual working of steel with which I can deal but briefly, notwithstanding their industrial importance. The points *a* and *b*, adopted in the celebrated memoir of Chernoff to which

1 "Études Métallurgiques," par Osmond, p. 6 (Paris: Dunod, 1888.)
2 Trans. American Soc. Civil Engineers, xvi., 1887, p. 324.

1 Trans. American Society Mechanical Engineers, ix., 1888, p. 155.
2 Proc. Roy. Soc., xlv., 1889, pp. 318, 445, and 457.
3 Proc. Inst. Civil Engineers, xciii. Part iii., 1888.

I have referred already, change in position with the degree of carburization of the metal. It is useless to attempt to harden steel by rapid cooling if it has fallen in temperature below the point (in the red) *a*, and this is the point of "recalescence" at which the carbon combines with the iron to form carbide-carbon: it is called V by Brinell. In highly carburized steel, it corresponds exactly with the point at which Osmond considers that iron, in cooling slowly, passes from the β to the α modification. Now with regard to the point *b* of Chernoff. If steel be heated to a temperature above *a*, but below *b*, it remains fine-grained however slowly it is cooled. If the steel be heated above *b*, and cooled, it assumes a crystalline granular structure whatever the rate of cooling may be. The size of the crystals, however, increases with the temperature to which the steel has been raised.

Now the crystalline structure, which is unfavourable to the steel from the point of view of its industrial use, may be broken up by the mechanical work of forging the hot

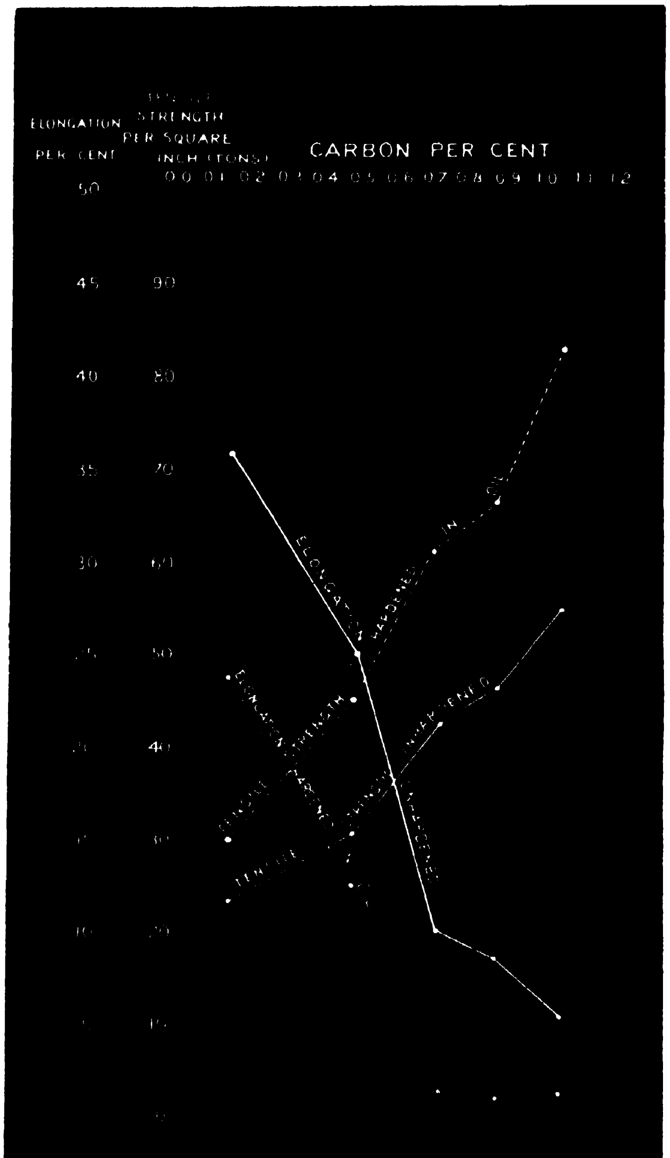

FIG. 11 shows the way in which the tenacity of steel containing varying amounts of carbon is increased by oil hardening,[1] while at the same time the elongation rapidly diminishes.

mass; and the investigations of Abel, of Maitland, and of Noble, have shown how important "work" on the metal is. When small masses of hot steel are quenched in oil, they are hardened just as they would be if water were used as a cooling fluid. With large masses, the effect of quenching in oil is different. Such cooling of large hot masses appears to break up this crystalline structure in a manner analogous to mechanical working. If the mass of metal is very large, such as a propeller shaft, or tube of a large gun, the change in the relations between the carbon and the iron, or true "hardening" produced by such oil treatment is only effected *superficially*—that is, the hardened layer does not penetrate to any considerable depth, but the innermost parts are cooled more quickly than they otherwise would have been, and the development of the crystals, which would have assumed serious proportions during slow cooling, is arrested. It depends on the size of the quenched mass, whether the tenacity of the metal is or is not increased, but its power of being elongated is considerably augmented. This prevention of crystallization I believe to be the great merit of oil quenching, which, as regards large masses of metal, is certainly not a true hardening process.

There has been much divergence of view as to the relative advantages of work on the metal, and of oil-hardening, but I believe it will be possible to reconcile these views, if the facts I have so briefly stated be considered.

The effect of annealing remains to be dealt with. In a very complicated steel casting, the cast metal probably contains much of its carbon as hardening carbon, and the mass which has necessarily been poured into the mould at a high temperature is crystalline. The effect of annealing is to permit the carbon to pass from the "hardening" to the "carbide" form, and, incidentally, to break up the crystalline stucture, and to enable it to become minutely crystalline. The result is that the annealed casting is far stronger and more extensible than the original casting. The carbide-carbon is probably interspersed in the iron in fine crystalline plates, and not in a finely divided state. It would obviously be impossible to "work"—that is, to hammer—complicated castings, and the extreme importance of obtaining a fine crystalline structure by annealing, with the strength which results from such a structure, has been abundantly demonstrated by Mr. J. W. Spencer, whose name is so well known to you all in Newcastle.

The effect of annealing and tempering is in fact very complicated, and I can only again express my wish that it were possible to do justice to the long series of researches which Barus and Strouhal have conducted in recent years. They consider that, annealing is demonstrably accompanied by chemical change, even at temperatures slightly above the mean atmospheric temperature, and that the "molecular configuration of glass-hard steel is always in a state of incipient change, . . . a part of which change must be of a permanent kind." Barus says "that during the small interval of time within which appreciable annealing occurs, a glass-hard steel rod suddenly heated to 300° is almost a viscous fluid."[1] Barus considers that glass-hard steel is constantly being spontaneously "tempered" at the ordinary temperature, which, he says, "acting on freshly quenched [that is hardened] steel for a period of years, produces a diminution of hardness about equal to that of 100° C., acting for a period of hours."

The nature of the molecular change is well indicated in the long series of researches which led them to conclude that in steel "there is a limited interchange of atoms between molecules under stress, which must be a property common to solids, if, according to Maxwell's conception, solids are made up of configurations in all degrees of molecular stability."

Barus and Strouhal attach but little importance to the change in the relations between the carbon and the iron during the tempering and annealing of hard steel. They consider that in hardening steel the "strain once applied to steel is locked up in the metal in virtue of its

[1] This was well shown in Prof. Akerman's celebrated paper on "Hardening Iron and Steel," Journ. Iron and Steel Institute, 1879, Part ii. p. 501.

[1] *Phil. Mag.*, xxvi., 1888, p. 209.

viscosity"; tempering is the release of this molecular strain by heat.

Highly carburized steels harden very energetically by very slight modifications in thermal treatment, and it will be evident that a very hard material is unsuitable for industrial use if the conditions of its employment are such as to render it desirable that the material should stretch. To turn to very "mild" steel which does not harden, it is certain that, although wrought iron passes almost insensibly into steel, there can be no question that not merely the structural but the molecular aggregation of even steel containing only $\frac{2}{10}$ per cent. of carbon is profoundly different from that of wrought iron. Formerly, as Sir F. Bramwell pointed out in a lecture delivered at the Royal Institution in 1877, "by the year 1830 . . . from small beginnings in Staffordshire and at Birkenhead sprang a wonderful *wrought-iron* navy, but steel was a luxury: it was made in small portions sold at high prices, as much as a shilling or eighteenpence a pound. It was employed for swords, cutlery, and tools, needles and other purposes where the quantity used was but trifling, and where the importance of the superior material was such as to justify the large expenditure incurred. It was felt in those days that steel was worth paying for because it was trusted; indeed its trustworthiness had passed into a proverb"—"as true as steel."

The class of steel which was formerly employed, as I have just indicated, for weapons and tools belonged to the highly carburized, readily-hardening class. It was the "mild steel" containing but little carbon which was destined to replace wrought iron, and when attempts were made to effect the general substitution of steel for iron, fears as to its character and trustworthiness unfortunately soon arose, so that from about the year 1860 until 1877 steel was viewed with suspicion. We can now explain this. Doubts as to the fidelity of steel, even when it was obtained free from entangled cinder, arose from ignorance of the fact that, on either side of a comparatively narrow thermal boundary, the iron in steel can practically exist in two distinct modifications. The steel was true enough, but from the point of view of the special duties to be intrusted to it, its fidelity depended on which modification of iron had to be called to the front. Artificers attempted to forge steel after it had cooled down below the point a of Chernoff, at which recalescence occurs, and they often attempted to work highly carburized steel at temperatures which were not sufficiently low.

Steels may be classified from the point of view of their industrial use according to the amount of carbon they contain, and I have attempted to arrange in this trophy certain typical articles, grouped under certain definite percentages of carbon ranging from $\frac{2}{10}$ to $1\frac{1}{2}$ per cent. [This was a trophy 18 feet square, with various typical articles of steel arranged in order according to the amount of carbon they contained. I am greatly indebted to Mr. J. W. Spencer, of Newcastle, who kindly lent me the fine series of specimens of which the "trophy" is built up.] Each class merges into the other, but the members at either end of the series vary very greatly. It would be impossible to make a razor which would cut from boiler plate; and conversely, a boiler made of razor steel would possibly fracture at once if it were superheated and subjected to any sudden pressure of steam. Speaking generally, if the steel contains, in addition to carbon, $\frac{5}{10}$ per cent. of manganese, each class of steel, as at present arranged, would have to be shifted a class backwards towards the left of the trophy.

At the present day, instead of steel being manufactured and used in small quantities, about 4,000,000 tons are annually employed in this country. Let us see how it is used. A steel fleet, the finest fleet in the world, has recently assembled at Spithead. The material of which it was made contained $\frac{15}{100}$ to $\frac{2}{10}$ per cent. of carbon, and when steel faces are used for the armour plates, the material contains $\frac{7}{10}$ to $\frac{8}{10}$ per cent. of carbon.

It has been pointed out that the crews of the fleet at Spithead numbered no less than 21,107 men. This it has been shown is "a remarkable figure, considering the great economy in men which prevails in a modern navy as compared with the navy of Nelson's day. A hundred years ago the normal requirements of a fleet were one man to a little over four tons, but now, thanks to the part played by steel and hydraulic power, we require but one man to every seventeen tons. Thus it may roughly be said that an aggregate of 20,000 men at the present day corresponds to an aggregate of 80,000 men in the days of Nelson." The latest type of battle-ship weighs, fully equipped, about 10,000 tons, there being about 3400 tons of steel in the hull, apart from her armour, which, with its backing, will weigh a further 2800 tons.[1]

From the use of steel in the Royal Navy and in the mercantile marine, let us pass on to its most notable use in construction. If the President of the French Republic was justified in appealing, in a recent speech, to the Eiffel Tower as "a monument of audacity and science,"[2] what are we to say of the Forth Bridge, the wonders of which will be described by Mr. Baker on Saturday? By his kindness I am able to place in the position in the trophy justified by the carbon it contains, a plate from the Forth Bridge, which fell from a height of some 350 feet, and, being of excellent quality, doubled itself on the rocks below. A single span of the Forth Bridge is nearly as long as two Eiffel Towers turned horizontally and tied together in the middle, and the whole forms a complicated steel structure weighing 15,000 tons, erected without the possibility of any intermediate support, the lace-like fabric of the bridge soaring as high as the top of St. Paul's. The steel of which the compression members of the structure are composed contains $\frac{23}{100}$ per cent. of carbon and $\frac{60}{100}$ per cent. of manganese. The parts subjected to extension do not contain more than $\frac{19}{100}$ per cent. of carbon.[3]

Time will not permit me to pass the members of each class in review. I can only refer to very few. Steel for the manufacture of pens contains about $\frac{3}{10}$ per cent. of carbon, and 16 to 18 tons of steel are every week let loose on an unoffending world in the shape of steel pens.

Steel rails contain from $\frac{3}{10}$ to $\frac{4}{10}$ per cent. of carbon, and, in this class, slight variations in the amount of carbon are of vital importance. An eminent authority, Mr. Sandberg, tells us that in certain climates a variation of $\frac{1}{10}$ per cent. in the amount of carbon may be very serious. The great benefit which has accrued to the country from the substitution of more durable steel rails for the old wrought-iron ones may be gathered from the figures which Mr. Webb, of Crewe, has given me, which show that "the quantity of steel removed from the rails throughout the London and North-Western system by wear and oxidation is about 15 cwt. an hour, or 18 tons a day."

Gun-steel contains $\frac{3}{10}$ to $\frac{5}{10}$ per cent. of carbon, and it may contain $\frac{8}{10}$ per cent. of manganese. It is in relation to gun-steel that oil-hardening becomes very important. The oil-tank of the St. Chamond Works (on the Loire) is 72 feet deep, and contains 44,000 gallons of oil, which is kept in circulation by rotary pumps, to prevent the oil being unduly heated locally when the heated mass of steel is plunged into it.

Now with regard to projectiles. To quote some recent remarks of Lord Armstrong,[4] "the heaviest shot used in the *Victory* was 68 pounds, while in the *Victoria* it will be 1800 pounds; and, while the broadside-fire from the

[1] Address by Mr. Baker, Section G, British Association Report, 1885, p. 1182.
[2] *Times*, August 19, 1889.
[3] Journal of the Iron and Steel Institute, 1888, ii. p. 94.
[4] *Times*, August 3, 1889.

Victory consumed only 325 pounds of powder, that from the *Victoria* will consume 3000 pounds. The most formidable projectiles belong to the highly carburized class of steel. Shells contain 0·8 to 0·94 per cent. of carbon, and, in addition, some of these have 0·94 to 2 per cent. of chromium. The firm of Holtzer shows, in the Paris Exhibition, a shell which pierced a steel plate 10 inches thick, and was found, nearly 800 yards from the plate, entire and without flaw, its point alone being slightly distorted. Compound armour-plate with steel face, which face contains 0·8 per cent. of carbon, is, however, more difficult to pierce than a simple plate of steel.

[A prominent feature in the "trophy," among the class of highly carburized steels which contain over $\frac{7}{10}$ per cent. of carbon, was a fine suspended wire $\frac{8}{100}$ of an inch diameter, of remarkable strength, supporting a weight of 2¼ cwt., or a load of nearly 160 tons to the square inch. The strength of the same steel *undrawn*, would not exceed 50 tons to the square inch. A similar wire manufactured by the steel company of Firminy attracted much attention in the Paris Exhibition by supporting a shell weighing 1800 lbs., or a load of 158 tons per square inch.]

Lastly, I will refer to the highly carburized steel used for the manufacture of dies. Such a steel should contain 0·8 to 1 per cent. of carbon, and no manganese. It is usual to water-harden and temper them to a straw colour, and a really good die will strike 40,000 coins of average dimensions without being fractured or deformed; but I am safe in saying that if the steel contained $\frac{1}{10}$ per cent. too much carbon, it would not strike 100 pieces without cracking, and if it contained $\frac{1}{10}$ per cent. too little carbon, it would probably be hopelessly distorted, and its engraved surface destroyed, in the attempt to strike a single coin.

The above examples will be sufficient to show how diverse are the properties which carbon confers upon iron, but as Faraday said, in 1822, "It is not improbable that there may be other bodies besides charcoal capable of giving to iron the properties of steel." The strange thing is that we do not know with any certainty whether, in the absence of carbon, other elements do play the part of that metalloid, in enabling iron to be hardened by rapid cooling. Take the case of chromium, for instance: chromium-carbon steels can, as is well known, be energetically hardened, but Busek[1] has recently asserted that the addition of chromium to iron in the absence of carbon does not enable the iron to be hardened by rapid cooling. So far as I can see, it is only by employing the electrical method of Pepys that a decision can be arrived at as to the hardening properties of elements other than carbon.

A few words must be devoted to the consideration of the colours which, as I said (see *ante*, p. 11), direct the artist in tempering or reducing the hardness of steel to any determinate standard. The technical treatises usually give—not always accurately, as Reiser[2] has shown—a scale of temperature ranging from 220° to 330°, at which various tints appear, passing from very pale yellow to brown yellow, purples, and blues, to blue tinged with green, and finally to grey. Barus and Strouhal[3] point out that it is possible that the colour of the oxide film may afford an indication of the temper of steel of far greater critical sensitiveness than has hitherto been supposed. It is, however, at present uncertain how far time, temperature, and colour are correlated, but the question is being investigated by Mr. Turner, formerly one of my own students at the School of Mines.

That the colours produced are really due to oxidation was shown by Sir Humphry Davy in 1813,[4] but the nature of the film has been the subject of much controversy. Barus points out that "the oxygen molecule does not penetrate deeper than a few thousand times its own dimensions,[1] and that it probably passes through the film by a process allied to liquid diffusion. The permeable depth increases rapidly with the temperature, until at an incipient red heat the film is sufficiently thick to be brittle and liable to rupture, whereupon the present phenomenon ceases, or is repeated in irregular succession.

Looking back over all the facts we have dealt with, it will be evident that two sets of considerations are of special importance: (1) those which belong to the relations of carbon and iron, and (2) those which contemplate molecular change in the iron itself. The first of these has been deliberately subordinated to the second, although it would have been possible to have written much in support of the view that carburized iron is an alloy of carbon and iron, and to have traced with Guthrie the analogies which alloys, in cooling, present to cooling masses of igneous rocks, such as granite, which, as the temperature of the mass falls, throws off "atomically definite"[2] bodies, leaving behind a fluid mass of indefinite composition, from which the quartz and feldspar solidify before the mica. This view has been developed with much ability in relation to carburized iron by Prof. Howe, of Boston, who even suggests mineralogical names, such as "cementite," "perlite," and "ferrite," for the various associations of carbon and iron.

I am far from wishing to ignore the interest presented by such analogies, but I believe that the possibility of molecular change in the iron itself, which results in its passage into a distinctive form of iron, is at present the more important subject for consideration, not merely in relation to iron, but as regards the wider question of allotropy in metals generally.

Many facts noted in spectroscopic work will have, as Lockyer has shown, indicated the high probability that the molecular structure of a metal like iron is gradually simplified as higher temperatures are employed. These various simplifications may be regarded as allotropic modifications.

The question of molecular change in solid metals urgently demands continued and rigorous investigation. Every chemist knows how much his science has gained, and what important discoveries have been made in it, by the recognition of the fact that the elements act on each other in accordance with the great law of Mendeleeff which states that the properties of the elements are periodic functions of their atomic weights. I firmly believe that it will be shown that the relation between small quantities of elements and the masses in which they are hidden is not at variance with the same law. I have elsewhere tried to show[3] that this may be true, by examining the effect of small quantities of impurity on the tenacity of gold.

In the case of iron, it is difficult to say what property of the metal will be most affected by the added matter. Possibly the direct connection with the periodic law will be traced by the effect of a given element in retarding or promoting the passage of ordinary iron to an allotropic state; but "the future of steel" will depend on the care with which we investigate the nature of the influence exerted by various elements on iron, and on the thermal treatment to which it may most suitably be subjected.

Is it not strange that so many researches should have been devoted to the relations between carbon, hydrogen and oxygen in organic compounds, so few to the relations of iron and carbon, and hardly any to iron in association with other elements? I think that the reason for the comparative neglect of metals as subjects of research arises

from the belief that methods which involve working at high temperatures are necessarily inaccurate; but the school of Ste. Claire-Deville has shown that they are not, and there are signs among us that our traditional love for the study of metals is reviving. Of course it cannot be that chemists and physicists are afraid "that science will be degraded by being applied to any purpose of vulgar utility," for I trust that I shall at least have shown that the empire over matter, and the true advancement of science, which I suppose is the object of all research, may be as certainly secured in the field of metallurgy as in any other.

PROF. WEISMANN'S "ESSAYS."

PROF. WEISMANN'S suggestions are, with reason, universally recognized as being most important and valuable; nevertheless certain questions treated of by him seem to me to require further solution, and at present to constitute difficulties which oppose themselves to an entire acceptance of his hypotheses.

Death in the Metazoa is, according to him, due (new translation, Clarendon Press, p. 21) to the cells of their tissues having ceased to be able to reproduce themselves—in "the limitation of their powers of reproduction." Such a cessation may be an inevitable result of an excessive amount of work or efficiency on their part, and "the advantages gained by the whole organism" might, as he says (p. 61), "more than compensate for the disadvantages which follow from the disappearance of single cells."

But granting all this, how did such a process begin? Some Metazoon must have been the first to die through this failure of reproduction in its component tissue-cells. Yet if the Protozoa were, and are (as Prof. Weismann represents), naturally immortal, the first Metazoa must have been entirely composed of immortal cells, and therefore themselves potentially immortal. Granted that cell-aggregations become every now and then accidentally dissolved, that would be "accidental death." Why should natural death arise, and, if it did, what advantage could ensue from the failure of cell-reproduction? It could not benefit the race, because as yet there was no race, but only individual clusters of naturally immortal cells which had happened to divide imperfectly. The Professor tells us (p. 29) it is "conceivable that all cells may possess the power of refusing to absorb nutriment, and therefore of ceasing to undergo further division." But how and why should a cell begin, for the very first time, to practice this abstinence? That it should do so, is, of course, like many other things "conceivable," but to my judgment it does not appear credible. Of course when once we have a race of mortal organisms propagating by germ cells, it is easy enough to understand how such a race would be benefited by the death of the "useless mouths" belonging to it, and therefore by the cessation of the tissue-reproduction which leads to such death. The difficulty lies in the natural death of the very first Metazoa which ever lived. Here, as in so many cases, it is "the first step" which tries us. How, from this perennial race of microscopic immortals, are we to obtain our first Metazoon *naturally* mortal?

By the hypothesis, each component cell consists of a form of protoplasm which has the power of growing and dividing. It is not easy to see how the mere coalescence of such cells can lead any one, or any set, of such cells to acquire an altogether new power—that of reproducing the whole complex organism of which it has come to be a part? The Professor tells us (p. 27) that probably "these units soon lost their primitive homogeneity. As the result of mere relative position, some of the cells were especially fitted to provide for the nutrition of the colony, while others undertook the work of reproduction." Referring to *Magosphæra planula*, he says (p. 75):—

"Division of labour would produce a differentiation of the single cells in such a colony: thus certain cells would be set apart for obtaining food and for locomotion, while certain other cells would be exclusively reproductive." But how can the fact of a cell happening to fall into a position "especially fitted" for the performance of a certain function, lead to its performing this function? Supposing that the physical influences of the environment have modified the arrangement, or cohesion, size, or number of molecules in a cell, or modified their molecular motions, how can such influences give it a power, not of reproducing its thus "acquired" characters, or the characters of the cell before it becomes thus differentiated, but of reproducing the whole organism whereof it forms a part? Is it credible that any impacts and reactions thus occasioned should produce so marvellous a result? I do not know any phenomena in Nature which could warrant us in entertaining such a belief.

Of course, if we were dealing with races of creatures sexually reproduced, it is conceivable enough that, out of multitudinous, indefinite, minute accidental changes in the arrangements of the molecules of their germs, favourable arrangements might be selected in the struggle for life. But we are here concerned with nothing of the kind, but with the first appearance of the earliest Metazoa reproduced. If we meditate on the conditions affirmed by the Professor to have produced that origin, it will, I think, be clear that no hypothesis suggested by him will answer the question how any of the cells of the first coherent colonies came to reproduce, not such cells as their ancestors (or, rather, the earlier living portions of their very selves) had by countless processes of fission produced, but a whole "cell-colony," such as that whereof they had, by the hypothesis, for the first time come to form a part.

With respect to the immortality of Monoplastides and the question of death generally, he (the Professor) makes various remarks which do not appear to be satisfactory. The process of spontaneous fission, he says (p. 25), "cannot be truly called death. . . Nothing dies, the body of the animal only divides into two similar parts possessing the same constitution." Where such a perfect similarity exists we may say not only that there is no death, but also that there is no birth. In some of the Monoplastides, however, the relationship between parent and offspring does exist, but this, of course, need not necessarily involve death; as we see in higher species and in our own. But the fact that death does not take place during, or soon after, fission, does not prove that death never naturally occurs at all, and that the cell can balance its metabolism indefinitely. Very likely it may be able so to do, but this can hardly be affirmed to be an absolute certainty. What may be certainly affirmed is that reproduction by fission does not entail death to the degree that sexual reproduction entails it. But reproduction by gemmation may equally fail to entail death; as we see in the parthenogenetic Aphis and many Hydrozoa.

In *Euglypha* we can, as Prof. Weismann admits (p. 64), recognize the daughter cell (which is for a time without a nucleus, and we also find a very marked distinction between the segments of transversely dividing Infusorians; where one has to form a new mouth and the other a new anus.

After all that can be urged, then, in contrasting the multiplication by fission of Monoplastides with reproduction in the life-cycle of Polyplastides, there seems to me to be more of a true reproductive process in the former than the Professor is disposed to allow. In some *Heliozoa* and *Ciliata* we have all the complexity of indirect nucleus division by karyokinesis, while in *Euglypha* we have cell division without any antecedent separation of the nucleus into two parts. Of course it is easy enough to understand how a mere augmentation in bulk may overcome cohesion, how internal molecular arrangement may cause cleavage along definite lines, and, perhaps, even how such cleavage

may be insured through an increase of mass in proportion to a relatively diminishing surface nutrition. But such a division would be much simpler than a process of karyokinesis, and certainly than the formation of a new mouth and a new anus. Here there is no question of a part (p. 73) growing "to resemble the whole," comparable to the regrowth, by crystallization, to replace a fragment broken from a crystal. We have a whole which divides itself in such a way as to initiate and carry out a progressively increasing *difference*—a difference between the two parts dividing, and a difference (but a different kind of difference) between each such part and the previously existing whole.

Passing from the consideration of the immortality of Monoplastides to the mortality of Polyplastides, I cannot see my way to accept the Professor's definition (p. 114) of death: "An arrest of life, from which no lengthened revival, either of the whole or any of its parts, can take place," nor can I agree to his assertion (*loc. cit.*) that death "depends upon the fact that the death of the cells and tissues follows upon the cessation of the vital functions as a whole." If we cut up a *Begonia* plant or a *Hydra* into small parts, such an individual *Hydra* or *Begonia* cannot surely be considered as still alive, because fresh *Hydræ* or *Begoniæ* may spring from such fragments. Similarly with higher organisms, it would be preposterous to say that a man was not dead because a *post-mortem*, inferior kind of life—such as can alone be manifested in very lowly structures—was still persisting in the cells of his tissues!

No doubt, as the Professor says, we cannot have death without a corpse, but the tissues and cells of the corpse may still retain a certain sort of life without the corpse being any the less a corpse on account of that circumstance.

But if life of some sort may be, as we agree, affirmed of such cells, can we deny it absolutely (since no one comprehends it) even to the molecules of the cells? But body-tissues of lower Vertebrates may retain such life for a very long time. If, then, such a Vertebrate be devoured by another animal, who would venture to affirm that it is impossible that some of the micellæ or tagmata, or at least the molecules of some of the cells of the creature devoured may not pass, while still retaining a sort of life, into the tissues of the devourer? Even tagmata must be small enough to traverse the tissues, and can the possibility that they may enter into their composition while still living be dogmatically denied? May we not affirm the certainty of the death of the animal devoured till we are sure of the impossibility of the survival of any of the molecules of its cells?

No doubt the Professor would refer us to *Magosphæra* as presenting phenomena (so far as regards its cells) which support his view. He says (p. 126):—"The dissolution of a cell colony, with its component living elements, can only be death in the most figurative sense, and can have nothing to do with the real death of the individuals; it only consists of a change from a higher to a lower stage of individuality. . . . Nothing concrete dies in the dissolution of *Magosphæra*; there is no death of a cell colony, but only of a conception." But surely it cannot be the same thing "to exist in a coherent interrelated mass bound together by a common jelly," and "to exist in separate parts, living independently without interrelations, and not bound together by a common jelly." If there is here "death of a conception," there must be an external objective death corresponding therewith. *Magosphæra* is a very lowly organism, and its life can be very little better than that of a Monoplastid, because its structure is very little more complex. It is not wonderful, then, that there is very little difference between its existence and the existence of its *post-mortem* surviving cells. Yet the difference must be allowed to be, however diverse in degree, like that in the higher animals. Let us suppose that half a dozen higher animals could be so divided that no two cells remained in contiguity, yet that every cell could retain a *post-mortem* life such that by reuniting they could build up other individuals. Would it be reasonable to affirm that the higher animals thus segmented had not been *killed*, or that when their cells had reunited—possibly in very different combinations—the individual animals were the same ones as before? An extreme illustration often best seems to bring out the force and significance of a principle.

The *Orthonectides*, referred to (p. 126) by the Professor in controversy with Götte, hardly illustrate the question here discussed, but we note with much interest and satisfaction that he is inclined to regard them as arrested larvæ, Leuckart having found them[1] greatly to resemble the new-born young of *Distoma*, as Gegenbaur has found that the Dicyemids are like a stage in the development of the Platyhelminthes. If this interpretation is, as it probably is, correct, we have here an interesting example of what we find in such *Batrachians* as *Axolotl* and *Triton alpestris*. I am inclined to look at *Menobranchus*, *Proteus*, and *Siren* as larval forms which have now altogether ceased to assume what was once the adult stage of their existence.[2]

Prof. Weismann's hypothesis concerning heredity is certainly the best which has yet been proposed, but I have not met with any reference to that proposed by Sir Richard Owen forty years ago.[3] It is now out of date, and his references are not of course expressly to "germ-plasm," but to the contents of germ-cells. Nevertheless, there is an undeniable resemblance between the two hypotheses, and any interested in Prof. Weismann's would do well to read over Owen's small volume on the same problem.

But the complexity of Prof. Weismann's hypothesis is such as to approach, if it does not even exceed, that of pangenesis itself

He tells us (p. 191): "Every detail of the whole organism must be represented in the germ-plasm by its own special and peculiar arrangement of the groups of molecules," and (p. 146) that "the number of generations of somatic cells which can succeed one another in the course of a single life, is predetermined in the germ." Moreover none of these circumstances can be explained by any difference of quality,[4] but must be exclusively due to the size, number, and arrangement of the component parts. Now, if we consider what must be the complexity of conditions requisite to determine once for all in the germ the precise number of all the succeeding cells of epithelial tissue, including every one of the rapidly succeeding cells of glandular epithelium, and every blood corpuscle of the whole of life; to necessitate also every modification of structure which may successively appear in polymorphic organisms, which change again and again profoundly between the egg and the imago; to arrange, at starting, the successive very complex changes of arrangement which must be necessary to build up reflex mechanisms

1 "Zur Entwicklungsgeschichte des Lebereglels," *Zool. Anzeiger*, 1881, p. 99.

2 In this connection may be noted a passage which occurs on p. 266 of Prof. A. C. Haddon's excellent introduction to the study of embryology. Sollas is there quoted as saying that a longer mature life is possessed by those forms which are "saved from the drudgery of a larval existence." It would be interesting to know whether *Rana opisthodon* is longer lived than its congeners, since it has no tadpole stage of life.

3 See his work "On Parthenogenesis" (Van Voorst, 1849). There we read:—"Not all the progeny of the primary impregnated germ-cell are required for the formation of the body in all animals. Certain of its derivative germ-cells may remain unchanged and become included in the body which has been composed of their metamorphosed and diversely combined or confluent brethren; so included, any derivative germ-cell *or the nucleus* of

of a new germ-process from a secondary, tertiary, or quaternary derivative germ-cell or *nucleus*, I do not profess to explain; neither is it known how it operates in developing the primary germ-mass from the impregnated germ-vesicle of the ovum. In both we witness centres of repulsion and of attraction antagonizing to produce a definite result."

4 P. 101, where the existence of "quality" is denied.

capable, not only of compelling complex instinctive actions occurring at one time of life, but of so successively changing as to be able successively to make necessary the successively occurring very different instinctive actions of different periods of life, as *e.g.* in *Sitaris*. But this is by no means all. The arrangement of the molecules must be such as not only to effect all this, but also all the constitutional pathological inherited modifications which are to arise at different periods of life, and all the capabilities of reaction upon stimuli of every cell, of every tissue, and every predisposition an organism may possess—"predisposition" and "capacity" being nothing more than names for a certain collocation of particles so built up as inevitably to fall down into other collocations—upon shock and impact—the original collocation again being such as to insure not only that the first ensuing collocation from impact shall be of an appropriately definite kind, but that its definiteness shall be such as to insure that all the succeeding varied collocations from successive impacts shall also be appropriately definite. I confess I do not believe that such a collocation of particles is possible.[1]

This, however, is, after all, only a portion of the difficulty from complication, necessarily involved in Prof. Weismann's hypothesis of germ-plasm. For we have to consider the modifying effect on the germ-plasm produced by its effecting those developmental changes which it is its own business to effect. After speaking of the great complexity of the germ-plasm in higher animals, he goes on (p. 191) to say:—"This complexity must gradually diminish during ontogeny, as the structures still to be formed from any cell, and therefore represented in the molecular constitution of the nucleoplasm, become less in numbers; . . . the complexity of the molecular structure decreases as the potentiality for further development also decreases, such potentiality being represented in the molecular structure of the nucleus."

According to the hypothesis, the whole organism at every stage of its existence is but a collocation of molecules of different sizes most complexly arranged. Amongst them, during development, are the portions of germ-plasm, everywhere building up the increasingly complex structures of the developing body, while they themselves are simultaneously decreasing in complexity of composition. Now, it seems somewhat difficult to conceive of such a mass, which may thus be said to both decrease and increase simultaneously in complexity, both centripetally and centrifugally, and yet to preserve its complexity both centrally and sporadically, as must be the case in order to effect sexual reproduction and such repair of tissues after injury, as the organism may be capable of. Prof. Weismann continues:—"The development of the nucleoplasm during ontogeny may be, to some extent, compared to an army composed of corps which are made up of divisions, and these of brigades, and so on. The whole army may be taken to represent the nuceloplasm of the germ-cell: the earliest cell-division (as into the first cells of the ectoderm and endoderm) may be represented by the separation of the two corps, similarly formed, but with different duties: and the following cell-divisions by the successive detachment of divisions, brigades, regiments, battalions, companies, &c.; and as the groups become simpler so does their sphere of action become limited. It must be admitted that this metaphor is imperfect in two respects: first, because the quantity of the nucleoplasm is not diminished, but only its complexity; and, secondly, because the strength of an army chiefly depends upon its numbers, not on the complexity of its constitution." A better illustration of the Professor's conception would seem to be that of an army very complexly organized sending off successively regiments of different kinds, but always retaining in the centre a few men of all arms, and always being recruited by rustics (the food of the germ-plasm), who become organized by the central reserve of all arms retained for that purpose.

But how, according to this or any other conceivable illustration, are we to understand the germ-plasm becoming simplified by forming tissues and organs, and then regaining its complexity so as to be able to effect the various reparative growths which constantly take place after non-fatal injuries? Or if we are to deem that the germ-plasm only regains a portion of its complexity—one portion in one place, another in another—how can we conceive of the germ-plasm being so divided that each part of the body has just that portion of germ-plasm which is needed for its reproduction, in spite of that being the very portion which we might expect to have been exhausted, since it is it which has built up that part of the body.

Moreover, all these processes of succession, progression, simplification, and possible recomplication, of the germ-plasm itself, must, according to the hypothesis, have been laid down and necessitated in the first original collocation of the molecules of the germ. This seems to me to exceed the bounds of credibility.[1]

But if the hypothesis of germ-plasm be deemed one involving too much complexity for belief—that is, if the conditions supposed by it are deemed inadequate to explain the results of sexual ontogeny—the hypothesis seems yet more unsatisfactory with respect to processes of reparative growth and reproduction by gemmation. This is a subject the Professor has not yet expressly treated, and therefore some suggestions with respect to its difficulties may be welcome to him, as showing what elucidations some minds seem to require. He, however, tells us (pp. 197, 211, and 322) that such processes of growth are due to the presence of germ-plasm, and of course not so to hold would be to abandon his hypothesis. It is, however, difficult to understand how we can thus account for the reproduction of a human elbow with a joint structurally and functionally much as the old one (see "On Truth," pp. 170–171). Are we to understand that germ-plasm in all its complexity was there? If so, is it universally diffused through the organism as well as present in the sexual glands, and why does it not produce rather an embryo than an elbow-joint? If *not*, how comes it that the germ-plasm present happened to have the complexity needed to effect that which was, anatomically and physiologically, effected? With respect to germination generally, the Professor says (p. 322):—"The germ-plasm which passes on into a budding individual, consists, not only of the unchanged idioplasm of the first ontogenetic stage (germ-plasm), but of this substance altered so far as to correspond with the altered structure of the individual which arises from it, viz. the rootless shoot which springs from the stem or branches. The alteration must be very slight, and perhaps quite insignificant, for it is possible that the difference between the secondary shoots and the primary plant may chiefly depend upon the changed conditions of development,[2] which takes place beneath the earth in the latter case and in the tissues of the plant in the former."

[1] Prof. Weismann sees clearly enough the fatal complexity of the parallel hypothesis of Nägeli, who would explain all this by "conditions of tension and movement." "How many different conditions of tension," our author remarks (p. 182), "ought to be possessed by one and the same idioplasm, in order to correspond to the thousand different structures and differentiations of cells in one of the higher organisms? In fact, it would be hardly possible to form even an approximate conception of an explanation based upon mere conditions of tension and movement."

[1] The term "Zielstrebig," as one used to denote a practically teleological process which is not really teleological, is a remarkable example of the mode in which we are led to regard the invention of a new name as an *explanation*.

[2] The remarkable readiness with which the fertile mind of Prof. Weismann excogitates hypotheses on hypotheses to explain away difficulties is rather remarkably shown by the way in which he tries to obviate the objection to his view as to parthenogenesis, which arises from the fact that in the bee the same egg will develop into a drone or not, according as it has or has not been fertilized. This would seem to emphatically contradict his doctrine, that the one cause of parthenogenesis is the greater amount of germ-plasm which exists in parthenogenetic eggs than in ordinary ones. He meets this by suggesting (p. 237) that if the spermatozoon reaches the egg it may, under the stimulus of *internal causes, grow to double its size*, thus obtaining the dimensions of the segmentation nucleus." What may *not* be thus explained?

Surely this is a very inadequate and even misleading statement of the matter. It is surely inconceivable that a portion of protoplasm should be affected in these diverse but most definitely diverse ways by the environment of earth and plant-tissues respectively. The radicle and plumule are formed (*e.g.* in the bean) while still surrounded by the tissues of the parent plant, but no radicle is formed in a growth by gemmation. Even if in all cases a radicle was formed, which radicle became largely developed under the stimulus of earth-environment, it would be difficult to understand why it should atrophy or metamorphose itself within those very plant-tissues under the influence of which it was itself first formed.

Again, as regards the Begonia leaf, if it is such germ-plasm as Prof. Weismann conceives of, which determines the development of such a leaf into a plant, what can be supposed to make it different from the germ-plasm of the seed? However complex may be the germ-plasm of Begonia, it must be a definite complexity. The germ-plasm cannot be simultaneously built up in two different ways. But a molecular arrangement which compels growth from a seed cannot possibly be the same as a molecular arrangement which compels growth from a leaf. The initial stages of the two processes are quite different.

Certainly the influence of the environment is sometimes very surprising; but these surprising results hardly, at least at first sight, seem to harmonize with Prof. Weismann's views. Thus the effect of the movements of the young of *Cynips*, newly hatched from an egg deposited in the tissues of a plant (p. 302), is to cause it to produce a gall—a result "advantageous to the larva but not to the plant." It causes "an active growth of cells" around the larva, much to that larva's advantage. Now surely it is too much to ask us to believe that the germ-plasm of the plant, in the first instance, before even, say, a single *Cynips* had visited it, had in the complex collocation of its molecules, an arrangement such as would compel the plant which was to grow from it, to grow these cells and form a gall as just mentioned.[1] However this may be, the production of the gall is certainly a curious effect of the action of the environment on an outgrowth from germ-plasm, conceived of as Prof. Weismann conceives of it.

But the question of the actual or possible influence of the environment suggests some further difficulties which can hardly fail to occur to any critical reader of what Prof. Weismann says concerning the inheritance of acquired characters. Although he absolutely denies that changes induced in the *soma* by the action of the environment, can be transmitted to a succeeding generation, he yet allows (p. 98) that the germ-plasm itself may be modified through the action of the environment on the *soma* increasing its nutrition, and such modifications, on his hypothesis, would be inherited. But if it is true, as stated, that oysters transported to the Mediterranean become rapidly modified, that the *Saturnia* imported to Switzerland from Texas become modified so as to transmit new characters in one generation, and that cats in Mombas, turkeys in India, and greyhounds in Mexico, have also been modified, their modifications being transmissible, it is very difficult to understand how such changed climatic conditions, or increased or diminished nutrition, could change the molecular structure of the germ-plasm in such a way as to compel the production in a second generation of modifications either so induced in the *soma* of the first, or of a nature appropriate to the conditions presented by a changed environment.

That the wild pansy does not change at once when planted in garden soil, and yet in the course of generations gains new characters which are propagated by seed, he explains (p. 433) by a modification of germ-plasm thus induced. But such an admission is enough to satisfy much of what is demanded by those who assert the inheritance of acquired characters. After all, such an inheritance must be due to the *soma*, since it is only through it that the germ-plasm can be modified.

If this effect on the germ-plasm itself is thus cumulative, may it not be partly due to a cumulative effect on the soma which transmits to the germ-plasm the actions which modify the latter? Can this be declared to be absolutely impossible? Anyhow, it is plain that effects of the environment on Polyplastides may be transmitted to succeeding generations. There are, however, still more striking phenomena amongst mammals which do not seem to accord with Prof. Weismann's theories. I refer to the production of offspring which resemble not their father, but the father of preceding offspring—as in the well-known case of Lord Zetland's brood mare, and the puppies of thoroughbred bitches which have once been coupled with a mongrel. How can the germ-plasm of the first father have been acquired by the offspring of a subsequent father? I have ventured to propose these questions, which must of course have occurred to many other naturalists, feeling sure that Prof. Weismann will be glad to have his attention drawn to a few points, a further explanation of which seems necessary for the acceptance of his most interesting hypotheses.

September 2. ST. GEORGE MIVART.

[1] It would be very interesting to know how "natural selection" (to the action of which, as everybody knows, Prof. Weismann constantly appeals) could have caused this plant to perform actions which, if not self-sacrificing (and there must be some expenditure of energy), are at least so disinterested. No doubt the Professor has an hypothesis to produce, though he only says (p. 302) here that "it would be out of place to discuss here the question."

NOTES.

THE Medals of the Royal Society have this year been awarded as follows:—The Copley Medal to the Rev. Dr. Salmon, F.R.S., for his various papers on subjects of pure mathematics, and for the valuable mathematical treatises of which he is the author; a Royal Medal to Dr. W. H. Gaskell, F.R.S., for his researches in cardiac physiology, and his important discoveries in the anatomy and physiology of the sympathetic nervous system; a Royal Medal to Prof. Thorpe, F.R.S., for his researches on fluorine compounds, and his determination of the atomic weights of titanium and gold; and the Davy Medal to Dr. W. H. Perkin, F.R.S., for his researches on magnetic rotation in relation to chemical constitution. Intimation has been received at the offices of the Royal Society that the Queen approves the award of the Royal Medals.

WE regret to learn that another officer of the Geological Survey of India has fallen a victim to the Indian climate. Mr. E. J. Jones, who joined the Survey in 1883, died of dysentery at Darjiling on October 15, at the age of thirty. Mr. Jones was an Associate of the Royal School of Mines, and having also studied chemistry at Zürich and Würzburg, he was a valuable member of the Survey, to the publications of which he contributed several geological and chemical papers.

To add to the many obligations under which he has laid Cambridge University, Prof. Sidgwick has offered to give £1500 towards the completion of the new buildings urgently required for physiology, on condition that the work is undertaken forthwith. The Financial Board has accordingly recommended a scheme by which this can be effected. The alliance between mental science and physiology which this gift represents is a bright feature of Cambridge studies at present.

THE University of St. Andrews is to be congratulated on an extraordinary piece of good fortune. The sum of £100,000 has been bequeathed to it by Mr. David Berry, who died last September. Mr. Berry was a native of Cupar, Fife, and in 1836 went to Australia, where he ultimately inherited the estate of his brother, Dr. Alexander Berry. The latter had been a

student of the St. Andrews University, and at the time of his death it was understood that he had left an unsigned will bequeathing a quarter of a million to his *alma mater*, but giving permission to his brother David to carry out the provisions as he might think proper. The legacy will not come into the possession of the University until 1894.

In addition to the botanical appointments named last week, the following are announced from Russia:—Prof. Faraintzin having resigned his post of Professor of Botany in the University of St. Petersburg. Prof. Borodin has been appointed in his place. M. W. Palladin succeeds the late Prof. Pitra as Professor of Botanical Anatomy and Physiology in the University of Charkow; and is himself succeeded in the Botanical Chair in the Agricultural Academy at Nowo-Alexandria by M. Chmielewski. M. W. Rothert has been appointed Lecturer on Botanical Anatomy and Physiology at the University of Kasan.

In the November number of the *Kew Bulletin* a curious correspondence is printed which illustrates very well the nature of some of the duties undertaken by the Kew officials. Towards the end of December 1876, Dr. Hooker received from the Colonial Office a letter inclosing a despatch in which the Governor of Labuan suggested that it might be well to promote in Labuan the cultivation of the African oil palm. A long correspondence followed, the result of which was that full and accurate information as to the palm oil industry was obtained from the Gold Coast, and transmitted to Labuan. Palm oil nuts were also obtained, and in due time planted in the fertile island of Daat, where no fewer than 700 healthy trees were soon raised. It recently occurred to Mr. Thiselton Dyer to make inquiry as to the later history of this interesting experiment. A despatch from the Acting Governor of Labuan to the Colonial Office, dated August 1, 1889, and forwarded to Kew, closes the correspondence. It is as follows:—"As reported in Mr. Treacher's despatch No. 72, of August, 26, 1878, it appears that 700 of these palms were raised in the island of Daat, and in due time produced nuts. No attempt, as far as I am aware, was ever made to manufacture any oil from the nuts, and last year the palms were all removed to make room for cocoa-nut trees. Daat, a dependency of this colony, is private property, and I venture to suggest that, should any further information be required by Mr. Thiselton Dyer, he should apply to the owner, Dr. Peter Leys, who is now in England, and who would no doubt be glad to supply it. The experiment, so far as I am in a position to judge, was a success."

The authorities of the Royal Gardens, Kew, are always glad to aid any dependency of the Empire in introducing and establishing any new plant which promises to serve as the foundation of a new industry. The documents relating to the oil palm in Labuan show how much work may be involved in the carrying out even of a simple scheme of this nature, and how disappointing the results may be. "The enterprise," says the *Bulletin*, "is suggested; it is considered; a plan for carrying it out has to be matured; all the necessary incidental information has to be collected; and then the plan is carried into execution. Sometimes it fails the first time, and then a second attempt has to be made, and so on till success is secured. All that then remains is to wait for the result; and this, in any appreciable shape, will in most cases not be reached for years. But in the interval Governors and officials change. It may be, though it is not always so, that the ardour with which the experiment was launched evaporates with the individual whom it inspired. A new Colonial Government *régime* may regard with apathy and even hostility the work of its predecessor, and the whole enterprise may fall into oblivion, till some chance inquiry on the same subject leads to the digging out of the file of papers containing its record from the Kew archives."

The remaining contents of the *Kew Bulletin* relate to Phylloxera regulations at the Cape, Ramie or Rhea, and the collecting and preserving of fleshy Fungi.

The Manchester Field Naturalists' Society has formed a special committee, with Mr. Leo Grindon, the President of the Society, as botanical referee, and Mr. C. J. Oglesby, as convener, for the purpose of determining which trees, shrubs, and flowers will succeed in the squares and streets of the city. The opinion prevails that, notwithstanding the unfavourable climatic conditions, several forest trees, climbers, and hardy plants would grow if special care were taken in planting and tending them. The planting of the quadrangle at Owens College, of the infirmary esplanade (in the centre of the town), and of several churchyards, has been attended with success.

The following money-grants have been lately made by the Berlin Academy of Sciences:—£75 to Prof. Brieger, for continuation of his researches on the ptomaines; £60 to Dr. Krabbe, for investigation of the Cladoniaceæ of the Hartz; £30 to Dr. von Dankelmann, for utilization of meteorological observations at Finschhaven in New Guinea; £20 to Dr. Assmann, for measurements of air-temperature on the Säntis; £100 for publication of Prof. G. Finsch's work on Torpedineæ; £50 for publication of a memoir by Dr. Heiden, on the development of *Hydrophilus piceus*; £100 to Dr. Strehlmann, in Zanzibar, for prosecution of his faunistic researches in East Africa; £125 to Prof. Lepsius, of Darmstadt, for preparation of his geological map of Attica; £50 to Prof. Conwentz, for investigation of silicified wood in the island of Schonen; £75 to Dr. Fleischmann, of Erlangen, for researches in development; and the same to Dr. Zacharias (Silesia), for micro-faunistic studies.

The first meeting of the one hundred and thirty-sixth session of the Society of Arts will be held on Wednesday, November 20, when the opening address will be delivered by the Duke of Abercorn, Chairman of the Council. Before Christmas there will be four ordinary meetings, in addition to the opening meeting. The following arrangements have been made:—November 27, Dr. J. Hall Gladstone, F.R.S., "Scientific and Technical Instruction in Elementary Schools"; December 4, Dr. Armand Ruffer, "Rabies and its Prevention"; December 11, Mr. H. Trueman Wood, "The Paris Exhibition"; December 18, Sir Robert Rawlinson, "London Sewage."

A novel and interesting application of science to art may now be seen at the Arts and Crafts Exhibition, where Mrs. Watts Hughes shows specimens of what she calls "voice figures" (Catalogue, No. 723). These are practically Chladni's figures produced in a viscid medium. Semi-fluid paste is spread on an elastic membrane stretched over the mouth of a receiver. A single note "steadily and accurately sung" into the receiver throws the paste into waves and curves. The patterns formed are either photographed immediately after production, or are transferred as water-colour impressions while the membrane is still vibrating. Fanciful names, *e.g.* "wave, line, flower, tree, fern," are given to these; the effect, especially in transparencies, is very beautiful. Some of the forms would repay the study of physicists as well as of artists; the most interesting are perhaps the "daisy forms," in which we are told that "the number of petals increases as the pitch of the note which produces them rises." The apparatus employed is not exhibited, and the descriptive label is not very clear, but we understand that Mrs. Hughes would be most pleased to explain the matter to anyone scientifically interested in it: her address is 19 Barnsbury Park, N.

FOR determination of the air-temperature at great heights, the Berlin Society for Ballooning (we learn from *Humboldt*) is going to try a method of Herr Siegsfeld, who uses a thermometer, which, by closure of an electric circuit when certain temperatures are reached, gives a light-signal. Small balloons, each containing such a thermometer, will be sent up by night, and the light will affect photographically a so-called "photo-theodolite," while the height then attained will be indicated in a mechanical way. It is hoped that more exact formulæ for the decrease of temperature with height may thus be obtained.

THE rapid decrease in the number of kangaroos is beginning to attract the attention of scientific Societies in Australia. From the collective reports of the various stock inspectors it was estimated that in 1887 there were 1,881,510 kangaroos. In 1888 the number fell to 1,170,380, a decrease of 711,130. The chief obstacle to the adoption of measures for the effectual protection of the kangaroo is his vigorous appetite. One full-grown kangaroo eats as much grass as six sheep; and graziers—who as a class are not, it is to be feared, readily accessible to the influence of sentiment—find that the food eaten by this interesting animal might be more profitably utilized otherwise. In a communication on the subject, lately submitted to the Linnean Society of New South Wales, Mr. Trebeck suggested that the National Park might be used for the preservation not only of kangaroos but of very many members of the Australian fauna and flora.

AT the monthly meeting of the Royal Society of Tasmania on September 9, the President (His Excellency Sir Robert G. C. Hamilton) said he desired to bring before the Society a matter relating to the young salmon at the Salmon Ponds. These were the undoubted product of the ova brought out by Sir Thomas Brady, which had been stripped from the male and female fish and artificially fertilized, and the utmost care had been taken to keep them apart from any other fish bred in the ponds. He recently visited the ponds, accompanied by the Chairman of the Fisheries Board, the Secretary, and two of the members, when they carefully examined a number of the young salmon, among which they were surprised to find marked differences existing, not only in size, but in their characteristics. It has often been held that the *Salmonidæ* caught in Tasmanian waters cannot be true *Salmo salar* because so many of them have spots on the dorsal fin, and a tinge of yellow or orange on the adipose fin, but nearly half of the young salmon they examined, which had never left the ponds, had these characteristics. Again, many of them were almost "bull-headed" in appearance—another characteristic which is not supposed to distinguish the true *Salmo salar*. He would suggest to the Chairman of the Fisheries Board, whom he saw present, that the Secretary should be asked to make a formal report of the result of this visit, and to obtain some specimens of the young fish, which could be preserved in spirits, and perhaps sent to Sir Thomas Brady to be submitted for the consideration and opinion of naturalists at home.

AT the same meeting of the Tasmanian Royal Society, Mr. James Barnard read a remarkably interesting paper on the last living aboriginal of Tasmania. It has hitherto been generally believed that the aboriginal Tasmanians are extinct. Mr. Barnard, however, contends that there is still one survivor—Fanny Cochrane Smith, of Port Cygnet, the mother of six sons and five daughters, all of whom are living. She is now about fifty-five years of age. Fanny's claims to the honour of being a pure representative of the ancient race have been disputed, but Mr. Barnard makes out a good case in her favour. He himself remembers her as she was forty years ago, when there were still about thirty or forty natives at Oyster Cove; "and certainly at that time," he says, "I never heard a doubt expressed of her not being a true aboriginal."

THE Caucasus is a region of great interest in the study of prehistoric times, and a fresh impulse was lately given to its exploration, by Beyern's discovery of an extensive burial-ground south of Kura (in the district of the Anticaucasus). At the recent annual meeting of the German Anthropological Society, Dr. Virchow gave some account of this bed (which Beyern has named after General Repkin). The region is rich in ores, but bronze articles are absent; for, while copper is plentiful, there is no tin. On the other hand, various ornaments of pure antimony have been met with; also antimony buttons (or knobs), like those of Beni-Hassan in Egypt. The ground is largely of volcanic nature, and many articles of obsidian (chiefly knives and arrow-heads) have been found in the graves. One curious find was that of a skeleton having an arrow-head of obsidian in one of the leg-bones, partly overgrown by a callus. The metallic girdles in this burial-ground have figures of animals engraved on them; in the Koban ground, such figures are confined to the clasp, but this, in the Repkin ground, is wanting.

PROF. EDWIN J. HOUSTON contributes to the November number of the Journal of the Franklin Institute a short paper on a hail-storm at Philadelphia, October 1, 1889. After noting various points common to most hailstones, he refers to a characteristic which he had never before observed. "On some of the hailstones," he says, "though not in the majority of them, well-marked crystals of clear transparent ice projected from their outer surfaces for distances ranging from an eighth to a quarter of an inch. These crystals, as well as I could observe from the evanescent nature of the material, were hexagonal prisms with clearly-cut terminal facets. They resembled the projecting crystals that form so common a lining in geodic masses, in which they have formed by gradual crystallization from the mother-liquor. They differed, however, of course, in being on the outer surface of the spherules."

IN *Das Wetter* for October, Dr. W. J. van Bebber discusses a paper, by the late Prof. Loomis, on the rainfall of the earth. The following are noted as some of the conditions favourable to rain: (1) an unsettled state of the atmosphere, caused by unusually high temperature, with great humidity, a condition which occurs when the pressure is below the average value; (2) cold northerly or westerly winds on the west side of a depression, by which the winds on the east side receive a stronger impulse; (3) proximity to mountains, the ocean or large lakes; (4) deep depressions of small area and steep gradients. With regard to the rainfall which accompanies barometric depressions, it is found that in the United States, south of latitude 36° N., a rainfall of 2·5 inches occurs oftener on the east side than on the west side of a depression in the ratio of 2·6 : 1; on the eastern side of the Rocky Mountains, a rainfall of 9 inches occurs more frequently on the east than on the west of a barometric minimum, in the ratio of 6·2 : 1. In the North Atlantic Ocean, the ratios of large rain areas on the east and west sides of a depression are as 2·6 : 1; while in Europe a rainfall of 2·5 inches in twenty-four hours on the east and west sides of a depression occurs in the ratio of 2 : 1. The rainfall with a falling or rising barometer is also investigated.

WE have received the fifth and last part of vol. i. of M. Fabre's comprehensive "Traité Encyclopédique de Photographie" (Paris: Gauthier-Villars, 1889). The subject of lenses is considered in great detail, and the theory and use of diaphragms are fully gone into. The relation of the time of exposure to the subject and lens employed is also considered, and studios, dark rooms, and their various accessories are fully described and illustrated. From both the theoretical and practical point of view the work still bears out its original promise of becoming the most complete one on the subject.

A SECOND edition of Prof. Tait's "Light" (A. and C. Black) has been issued. The author says that in revising the work he has made use of various notes jotted down from time to time on his own copy, mainly as the result of questions asked, or of difficulties pointed out, by students who were reading the book with care. Suggestions of this kind he has found to be almost always of value, as they tend to make the book better suited to the wants of the class of readers for whom in particular it was designed.

PERSONS interested in ferneries and aquaria will find much to attract them in a little volume entitled "Ferneries and Aquaria: a Complete Guide to their Formation, Construction, and Management," by George Eggett, Sen. This is one of a series of "practical guide-books" issued by Messrs. Dean and Son.

THE third volume (new series) of the *Reliquary* (Bemrose and Sons) has been issued. It opens with an interesting illustrated article on two Assyro-Phœnician shields from Crete, by the Rev. Joseph Hirst. Mr. John Ward contributes three illustrated papers of scientific value—on Rains Cave, Longcliffe, Derbyshire; on relics of the Roman occupation, Little Chester, Derby; and on recent diggings at Harborough Rocks, Derbyshire.

MESSRS. DULAU AND CO. have sent us a "Catalogue of Zoological and Palæontological Works." It includes works on Reptilia and Amphibia, and on Pisces.

THE atomic weight of palladium has been redetermined by Dr. E. H. Keiser (*Amer. Chem. Journ.*). Among all the atomic weights at present adopted by chemists, that of palladium has been one of the most imperfectly determined, for the discrepancy between the results of the various previous investigations is most unsatisfactory. In 1826, Berzelius obtained the value 113·63 from a consideration of the proportion in which palladium combines with sulphur. Two years later, the same distinguished chemist derived a much lower value from analyses of potassium palladious chloride, $2KCl \cdot PdCl_2$; known quantities of this salt were heated in a current of hydrogen, and the residuary potassium chloride and reduced palladium weighed. Recalculated by Profs. Meyer and Seubert, utilizing all the refined corrections of the present day, these analyses yield the value 106·2—a number which is almost identical with the atomic weight obtained by Dr. Keiser. In 1847, however, Quintus Icilius also investigated the subject, and, from determinations of the loss in weight which potassium palladious chloride undergoes when heated in a current of hydrogen, obtained the value 111·88. No other determinations having since been attempted, and the number 112 or 113 being certainly too high from considerations of the position of palladium among the metals, the number 106·2 obtained from Berzelius's second analysis recalculated by Meyer and Seubert has been universally adopted. To place the subject out of all doubt, Dr. Keiser has re-examined it from a totally different standpoint. The double chlorides of palladium and the alkalies, such as $2KCl \cdot PdCl_2$ and $2NH_4Cl \cdot PdCl_2$, are found to be unsuitable for atomic weight determinations; they retain water of decrepitation with great tenacity, and, after drying, are too hygroscopic for accurate weighing. On the other hand, the yellow crystalline salt, palladammonium chloride, $Pd(NH_3)_2Cl_2$, is a much more suitable substance. It is eminently stable, can be obtained in a state of practically perfect purity, contains no water of crystallization, does not retain water after drying in a desiccator, and the dried salt is not hygroscopic. Weighed quantities of it contained in a platinum boat were introduced into a combustion tube and heated in a stream of pure hydrogen. The hydrogen was rapidly absorbed, changing the bright yellow colour into black, metallic palladium and ammonium chloride being formed. The absorption of hydrogen occurred so readily that it was only necessary to warm one end of the boat when the heat of the reaction was found sufficient to complete the reduction of the whole. $Pd(NH_3)_2Cl_2 + H_2 = Pd + 2NH_4Cl$. After raising the temperature so as to volatilize the ammonium chloride, the finely divided palladium adhered together in the form of a porous bar having the shape of the boat. It was allowed to cool before weighing until just below a red heat in the current of hydrogen so as to prevent oxidation, and afterwards the hydrogen was displaced by dry air to prevent its occlusion. Two series of determinations were made, the salt for the second series being prepared from the reduced palladium of the first. The mean of eleven experiments in the first series gave the number 106·352, and of eight in the second series 106·350. The maximum value obtained was 106·459, and the minimum 106·286. The mean result 106·35 practically confirms that obtained by recalculating the results of Berzelius's second analyses.

IN our note in these columns three weeks ago (vol. xl. p. 655), upon pinol, the new isomer of camphor, it was pointed out that the nitrosochloride of pinol forms with β-naphthylamine an interesting base, $C_{20}H_{24}N_2O_2$, isomeric with quinine. This base, however, is not the first isomer of quinine which has been prepared, for an artificially prepared base of the same empirical formula was described by Dr. Kohn, of University College, Liverpool, in the Journal of the Chemical Society for 1886, p. 500.

THE additions to the Zoological Society's Gardens during the past week include three Rhesus Monkeys (*Macacus rhesus* ♂ ♂ ♂) from India, presented respectively by Colonel Cuthbert Larking, Mr. James T. Wilson, and Mrs. Charles Sainsbury; a Hairy-rumped Agouti (*Dasyprocta prymnolopha*) from Guiana, presented by Mr. Henry E. Blandford; a Common Polecat (*Mustela putorius*) from Norfolk, presented by the Earl of Romney; a Northern Mocking Bird (*Mimus polyglottis*) from North America, presented by Miss E. Breton; two White Pelicans (*Pelecanus onocrotalus*), a Crested Pelican (*Pelecanus crispus*) from Roumania, a Common Boa (*Boa constrictor*), a Neck-marked Snake (*Geoptyas collaris*) from Panama, a Mocassin Snake (*Tropidonotus fasciatus*) from North America, deposited; two Common Siskins (*Chrysomitris spinus*), two Twites (*Linota flavirostris*), two Lesser Redpoles (*Linota rufescens*), four Snow Buntings (*Plectrophanes nivalis*), two Knots (*Tringa canutus*), a Bar-tailed Godwit (*Limosa lapponica*), British, a Rosy-billed Duck (*Metopiana peposaca* ♂) from South America, purchased.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at 10 p.m. at Greenwich, November 14 = 1h. 36m. 45s.

Remarks.

(1) This is one of Herschel's double nebulæ. Dr. Huggins notes that both components give a gaseous spectrum, but could only be certain of the presence of the chief nebula line near 500, although 495 was strongly suspected. He notes, also, that there

is a faint continuous spectrum at the preceding edge of No. 386. The point chiefly requiring attention at present is the character of the line near 500. Many recorded observations describe this line as having a fringe of light on the more refrangible side, whilst others state that it is perfectly sharp on both edges. Low dispersion only should be employed in making this observation. The observation of continuous spectrum in a special part of the nebula 386 is also worthy of attention; the spectrum should be examined for maxima of brightness, as in the case of the nebula in Andromeda.

(2) Dunér records this as a star of Group II. (see below), but states that the spectrum is very feebly developed. The star is probably, therefore, either just condensing into a fully-developed star of Group II., or is just passing into Group III. If the former, there will practically be nothing but very narrow bands, and if the latter, absorption *lines* will accompany the bands. In the earlier stages of this group, the bands in the blue are strongest, whilst in the later stages red bands are strongest, and this point should also receive attention. As a check, the colour of the star should be noted at the time of observation.

(3) This star belongs to either Group III. or to Group V., and the criteria (see p. 20) should be observed in order to determine which.

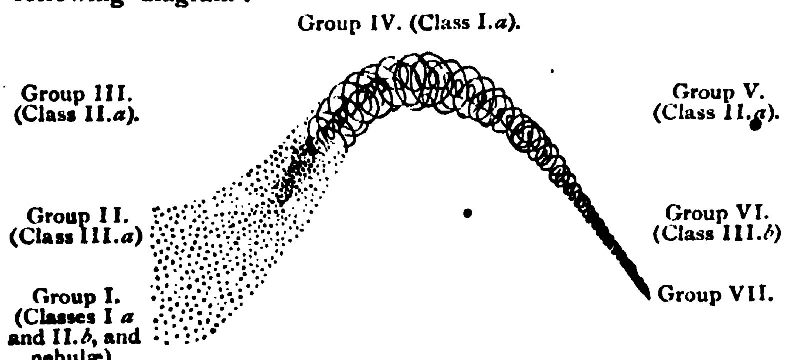
(4) According to Vogel, the spectrum of this star is of the same type as α Lyræ, *i.e.* Group IV. The relative intensities of the metallic lines and those of hydrogen, which vary from star to star, should be noted for future classification of the stars of this group according to temperature.

(5) This is a star of Group VI. Dunér describes the spectrum as consisting of four zones, the zones being the bright spaces between the dark carbon flutings. The presence of slight traces of carbon absorption in the solar spectrum indicates that stars of this group only differ in temperature from stars like the sun. The passage from one group to the other will probably be found to be very gradual, and the widths of the carbon flutings and the presence or absence of other absorptions should therefore be noted.

(6) Period given by Gore as 382 days, and magnitude at maximum (November 13) as 6·9–7·7. The spectrum has not yet been recorded, and the present maximum may, therefore, conveniently be taken advantage of.

(7) Period given by Gore as 168 days, and magnitude at maximum (November 15) as 8·3–9. Spectrum not yet recorded.

Note.—Lockyer's classification will, in future, be exclusively used, so that there will be no necessity for a double reference. The relation of this to Vogel's classification is shown in the following diagram:—



Lockyer's Temperature Curve.

The temperature increases from Group I. to Group IV., and then decreases to Group V. On the ascending side of the "temperature curve" we have probably to deal with condensing meteoritic swarms; and, on the descending side, with gradually condensing masses of meteoritic vapours.

A. FOWLER.

LARGE-SCALE CHARTS OF THE CONSTELLATIONS.—Mr. Arthur Cottam has projected a series of thirty-six most excellent charts of the constellations from the North Pole to between 35° and 40° of south declination, and showing stars in half magnitudes down to 6½ by disks of various sizes. Although the primary object in constructing these charts was to make them companions to Webb's "Celestial Objects for Common Telescopes" and Smyth's "Cycle of Celestial Objects," their scope has been considerably enlarged, and a number of double, multiple, and variable stars have been laid down which are not included in either of the above-mentioned works. The Earl of Crawford's (Dun Echt) summary of F. G. W. Struve's Dorpat Catalogue included 2248 double and multiple stars, and of them, 2130 are shown upon these charts. In addition to this, 275 of the double stars discovered by Mr. S. W. Burnham have been mapped, this being the whole of those included in his first four catalogues, and a selection from his other catalogues. The maps have been drawn to a scale of one-third of an inch to a degree, which is a much larger scale than any hitherto published, and as each map includes but a small portion of the heavens, there is practically no distortion, whilst the epoch being 1890, the positions will hold good, without any serious errors, for fifteen or twenty years beyond that date. The projection is conical, or, in those charts which extend any distance both north and south of the equator, cylindrical. Hence it will be easy to lay down any additional objects that may be required. There is no doubt that these charts will be eminently useful, one of their great advantages being that they will enable possessors of telescopes mounted on altazimuth stands or without circles to find with ease a large number of interesting objects, and thus will help to extend the knowledge of the heavenly bodies and to popularize the most fascinating of sciences. We may say that the publisher of these charts is Edward Stanford, Cockspur Street, S.W., and that the first issue is limited to 200 sets, many of which have been already subscribed for.

BARNARD'S COMET, II. 1889, MARCH 31.—The following ephemeris is given in *Astronomische Nachrichten*, No. 2931:—

1889.	R.A. h. m. s.	Decl. ° ′	1889.	R.A. h. m. s.	Decl. ° ′

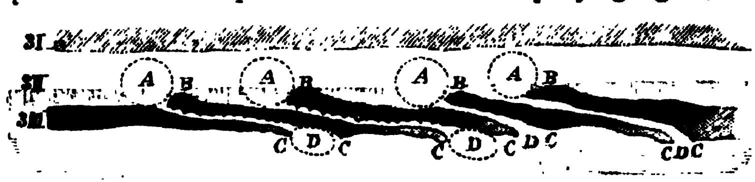
THE STRUCTURE OF JUPITER'S BELT 3, III.—This dark band appears under ordinary conditions to be made up of two parallel bands, but Dr. Terby (*Astronomische Nachrichten*, No. 2928) says this appearance of parallelism is the result of the special structure represented in the accompanying figure, and



Structure of Jupiter.

that, therefore, the band 3, III., is composed of a lot of dark bands inclined in the same direction. The circular parts A are distinguished by Dr. Terby as emitting a sort of diffused light of an entirely different character from the white equatorial spots, properly so called; these luminous balls seem always to occur at the interval between two of the inclined bands, and touching what is generally their darkest part, B. The brilliant white spots D also appear at the dissolution of two successive bands, and occupy by preference their northern extremities. When the definition was very good, Dr. Terby observed that the interval between two of these fragmentary bands had the appearance of a series of globules, as shown in the figure. The structure appears so general and regular that it may be the means of adding considerably to our knowledge of the physical constitution of this planet.

GEOGRAPHICAL NOTES.

AT the first meeting of the session of the Royal Geographical Society, the paper was on Cyprus, by Lieut.-General Sir Robert Biddulph, G.C.M.G., C.B. The island of Cyprus is the third largest in the Mediterranean, being inferior in size only to Sicily and Sardinia. Its area is 3584 square miles. Its principal

features are two mountain ranges, running pretty well parallel to each other from east to west. The northernmost of these two ranges extends almost the whole length of the island from Cape Kormakiti on the north-west to Cape St. Andrea at the end of the horn-like promontory which stretches for 40 miles from the north-east of the island. This promontory is called the Carpas, and the low mountain chain running through it is called the Carpas range. The westernmost and higher portion of the northern range is called the Kyrenia range, and rises to an altitude of 3340 feet. This range is of a remarkably picturesque outline, in some parts extremely rugged. It is mostly a single ridge without any remarkable spurs, and its summit is about two miles from the northern coast. It can be crossed in many places. The chief mountain peaks of this range are Kornos, 3105 feet; Buffavento, 3140; and Pentedaktylos, 2400. The last named is a remarkably shaped rock in the centre of the Kyrenian range, owing its name to its shape, the word Pentedaktylos signifying in Greek "five-fingered." Beneath this rock there rushes out southward from the mountain side, at an altitude of 870 feet, a torrent of water, which never ceases to flow summer or winter, and which, descending into the great plain in the centre of the island, carries its fertilizing streams to the lands of several villages, its course marked by mills, gardens, and trees, until its water is exhausted by various irrigating channels. A similar stream of water gushes from the northern side, about 12 miles west of the Kyrenia Pass. Smaller streams descend on either side of the range at various places; their waters are used for irrigation in the valleys. The southern range of mountains is of a much more extensive nature than the northern range. The easternmost point of this range is the mountain of Santa Croce, so called from the church of the Holy Cross which stands on its summit. This mountain, which is 2260 feet in height, is of a peculiar shape. Beginning then from this point the southern range rapidly rises to considerable altitudes, finally culminating in Mount Troodos, the highest point in Cyprus, being 6406 feet above the sea-level. The other chief peaks in the southern range, are Adelphe, 5305 feet; and Machera, 4674 feet. But it is not only in altitude that the Troodos range is distinguished; numerous spurs run down to the north and south, and as we proceed further west these radiate out to greater distances, so that half way between Troodos and the sea, the mountain range is not less than 20 miles wide. Here there are very considerable forests, many miles in extent, rarely visited save by wandering flocks and by wood-cutters, and affording shelter to the moufflon, or wild sheep of Europe, some 200 or 300 of which still roam over these hills. On the map it will be seen that numerous rivers descend from both sides of the southern range. These are mostly dry in summer, but after rain their waters descend with violence, filling up the river-beds in the plains, carryiny away trees and cultivated patches, and often rushing in a turbid stream into the bays of Famagusta and Morphou. Between the two mountain ranges there lies a great plain called the Mesaorea, which is the most fertile part of Cyprus, growing large crops of wheat, barley, and cotton. It was evidently once the bottom of the sea, for in many parts are large beds of marine shells—gigantic oysters and others—all clustered in masses. A noticeable feature of this plain is the number of flat-topped plateaux of various sizes, where the rock seems to have resisted the action of the water. The tops of these plateaux are clothed with short herbage, affording a scanty provision for flocks, and are usually from 100 to 200 feet above the plain. The rivers which descend from the hills carry down large quantities of alluvial soil, and this forms in the eastern part of the Mesaorea a rich deposit, something similar to the Delta of the Nile. The two rivers which mainly contribute to this plain are the Pediæus and the Idalia, the former taking its rise from the northern slopes of Mount Machera, and the latter from the eastern slopes of the same mountain. The beds of these rivers have, however, become so choked up with alluvial deposit towards the end of their course, that their waters overflow the plain and mingle together, so that their separate mouths can with difficulty be distinguished. The normal condition of these rivers is to be without water, but whenever there is a heavy rainfall in the mountains, the river "comes down," as it is called, and runs for one, two, or more days. It occasionally happens that the water descends with great suddenness and violence, causing disastrous floods. Considerable supplies of water for irrigation purposes are obtained by sinking wells. A long chain of wells are sunk at distances of five or six yards apart, and being connected by underground galleries, a channel is thus formed which conveys the water to a reservoir constructed at the foot of the last well, and it is thence raised to the surface by a water-wheel; or in some cases the level of the ground admits of the channel being brought out on the surface. In this way the town of Nicosia is supplied with excellent water, which is brought in two aqueducts from a distance of some miles. Larnaca and Famagusta and other towns have similar aqueducts. Closely connected with the water supply is the forest question. Sir Robert Biddulph then entered into detail with reference to the denudation of Cyprus of its forests, and the great locust-plagues which have been so successfully treated since the British occupation.

THE FLORA OF CHINA.[1]

SINCE the last meeting of the British Association, two additional parts of the "Index Floræ Sinensis" have been published, bringing the enumeration of known, and the description of new, species as far as the *Loganiaceæ*. The Committee now, therefore, look forward with some confidence to the completion of their labours at no distant date.

Further extensive and valuable collections have been received from China in aid of the work, more especially from Dr. Augustine Henry, late of Ichang. The novelty and richness of the material obtained by this indefatigable botanist far exceeds any expectations the Committee could have formed. It is to be regretted that his duties as an officer of the Chinese Imperial Maritime Customs have necessitated his removal to Hainan. It is probable, however, that he had practically exhausted the immediate neighbourhood of Ichang, and that without opportunities of travelling over a wider radius, which the Committtee regret they were unable to procure for him, he would not have been able to add much of material novelty to the large collections already transmitted by him to Kew.

The Committee have met with the kindest sympathy and assistance in their labours from Dr. C. J. de Maximowicz, of the Académie Impériale of St. Petersburg, who has long been engaged on the elaboration of the collections made by Russian travellers in China, and from M. Franchet, of the Muséum d'Histoire Naturelle at Paris, who is describing and publishing the extremely rich collections made by the French missionaries in Yunnan.

The Committee have received striking proofs of the appreciation of their labours by botanists of all countries. They permit themselves to quote the following passage from a letter received early in the present year from Baron Richthofen, than whom no one is more competent to estimate the value of work connected with the scientific exploration of China:—

"It is of great value to have, now, a Flora of China, embodying all the species known from that country. You have evidently succeeded at Kew in getting a very complete collection. At the same time, in looking over the localities mentioned in the book, it strikes me that large portions of China are still unexplored botanically. There remains a splendid field for a good collector in the Tsingling Mountains, the province of Sz'chuen, and chiefly its elevated region west of Ching-tu-fu. Work in those parts will be greatly facilitated by the solid foundation laid through the work of Forbes and Hemsley."

The Committee derive an independent existence as a Sub-Committee of the Government Grant Committee of the Royal Society. They are at present in possession of sufficient funds to enable them to carry on the work. They do not therefore ask for their reappointment at the hands of the British Association.

SCIENTIFIC SERIALS.

American Journal of Science, October.—Assuming that the earth's crust rests on a layer of liquid as a floating body, Mr. Le Conte here offers an explanation of normal faults. The crust is supposed to be raised into an arch, by intumescence of the liquid, caused by steam or hydrostatic pressure; it is thus broken by long more or less parallel fissures into oblong prismatic

[1] Third Report of the Committee, consisting of Mr. Thiselton-Dyer (Secretary), Mr. Carruthers, Mr. Ball, Prof. Oliver and Mr. Forbes, appointed for the purpose of continuing the preparation of a Report on our present knowledge of the Flora of China.

blocks, which, on relief of the tension by escape of lava or vapour, are readjusted by gravity, in new positions. The blocks may be rectangular in section, but are more likely to be rhomboidal or wedge-shaped; giving level tables with fault cliffs (as in the plateau region) in the one case, and tilted blocks with normal faults (as in the basin region) in the other. The author considers the Sierra and Wahsatch to have been formed by lateral crushing and folding; and the region between to have been arched, broken, and readjusted, as described, in the end of the Tertiary.—Two determinations of the ratio of the electromagnetic to the electrostatic unit are furnished from the Johns Hopkins University; one made this year, by Mr. Rosa, by Maxwell's method of measuring a resistance, the other ten years ago, by Messrs. Rowland, Hall, and Fletcher, by measuring a quantity of electricity electrostatically, and then measuring it electromagnetically with a galvanometer. The former gives $v = 2\cdot9993 \times 10^{10}$ centimetres per second; the latter, $2\cdot9815 \times 10^{10}$ centimetres. It seems certain, according to Mr. Rosa, that v is within a tenth per cent. of 300 million metres per second.—Mr Long continues his account of the circular polarization of certain tartrate solutions; and his experiments point to a law that the rotation of a double tartrate may be made to approach that of a neutral tartrate of either of the metals present, by addition of a salt of that metal (the effects being apparently explained by substitution).—Mr. Eldridge proposes a new grouping and nomenclature for the middle Cretaceous in America.—There are also papers on the gustatory organs of the American hare (Mr. Tuckerman); on the output of the non-condensing engine, as a function of speed and pressure (Mr. Nipher); and on some Florida Miocene (Mr. Langdon).

SOCIETIES AND ACADEMIES.

London.

Physical Society, November 1.—Prof. Reinold, F.R.S., President, in the chair.—The following communications were read:—On a new electric-radiation meter, by Mr. W. G. Gregory. The meter consists of a long fine platinum wire attached to a delicate magnifying spring of the Aryton and Perry type, and stretched within a compound tube of glass and brass. At the junction between the wire and spring a small mirror is fixed. When the tube is placed parallel to a Hertz's oscillator in action, the mirror is turned in a direction indicating an extension of the wire. The arrangement is so sensitive that an elongation of $\frac{1}{2000000}$ of a mm. can be detected, and when placed at a distance of 4 metres from the oscillator the apparent extension is such as would correspond to a change of temperature of 0°·003 C. By its aid the author has roughly verified Hertz's statements that at considerable distances the intensity of radiation varies as the inverse distance; but before he can proceed further it is necessary to greatly increase the sensibility of the apparatus; and with a view of obtaining some suggestions in this direction, he exhibited it before the Society. Prof. Perry asked if the E.M.F. required to produce the observed results had been calculated; he also believed that the sensibility might be increased by using copper instead of platinum wire, and replacing the spring by a twisted strip. Mr. Blakesley inquired whether the effect of increasing the capacity of the ends of the wire had been tried. Mr. Boys said that if the observed effect was due to rise of temperature he would like to see it measured thermally. He also thought the effect might be due to extension caused by rapid electric oscillations in some such way as the elongation of an iron bar caused by magnetization. In answer to this, Prof. S. P. Thompson said the matter had been investigated experimentally, but with negative results. Prof. Herschel suggested the use of a compound spring such as is used in Breguet's metallic thermometers. In reply, Mr. Gregory said he had estimated the E.M.F. by observing that a Leclanché cell through 50 ohms produced about the same result. No improvement in sensitiveness was obtained by using copper wire or by increasing its capacity, and attempts to measure the rise of temperature by an air thermometer had been given up as hopeless. The President, in thanking the author for his paper, congratulated him on the ingenuity and courage displayed in producing an apparatus to measure such microscopic quantities as are here involved.—On a method of driving tuning-forks electrically, by Mr. Gregory. In order to give the impulses about the middle of the stroke, the fork is arranged to make and break the primary circuit of a small transformer, the secondary circuit of which is completed through the electromagnet actuating the fork. The prongs of the fork are magnetized and receive two impulses in each period. Another device was suggested, where the prongs respectively operate contacts which successively charge and discharge a condenser through the coils of the actuating magnet. Prof. S. P. Thompson said the methods, if perfect, would be of great service, and suggested that a fork so driven be tested optically by comparison with a freely vibrating one. He regarded the mercury contacts used as objectionable, for their capillarity and adhesion would probably cause the impulses to lag behind the appointed epochs. Prof. McLeod remarked that Lissajous' figures gave a satisfactory method of testing the constancy of period, and could be readily observed without using lenses, and in reference to liquid condensers suggested by the author for his second device, said that platinum plates in sulphuric acid were found to disintegrate when used for this purpose. He thought lead plates would prove suitable. Prof. Jones, who read a paper on a similar subject in March last, said he now used bowed forks, with which to synchronize the speed of the disk there described, and the frequency is determined by causing the disk to complete the circuit of his Morse receiver once each revolution.—On a physical basis for the theory of errors, by Mr. C. V. Burton. After pointing out that the law of error for any particular measurement depends on the nature of the conditions governing such measurement, the author considers several simple cases, and deduces their curves of error. A kinematic method of combining two or more independent errors, each following known laws, is then described and applied, and the general formula obtained leads to Laplace's law of error in the case of an infinite number of similar errors. Referring to Most Advantageous Combinations of measures, it is shown that the method of least squares is only a particular solution of the general equation, and is derived by assuming the individual errors to conform to Laplace's law. Subjective errors are next considered, and in conclusion the author says that "the law of error in a set of observations depends on the nature of each special case, and what may be called the probable law of error is determined by our knowledge of the conditions. The combination of three or more sources of error of comparable importance gives in general a law not seriously differing from that of Laplace, so that the method of least squares will be practically the most advantageous, except where a single source of error with a very different law is predominant above all the rest."—A note on the behaviour of twisted strips, by Prof. J. Perry, F.R.S., had been prematurely announced by mistake, and he accordingly gave only a brief outline of the paper. In a previous communication, Prof. Ayrton and the author enunciated a working hypothesis in which the strips were imagined to be split up into pairs of filaments, each pair acting as a bifilar suspension. The resulting formula for the rotation produced by a given load did not agree with experiment, and quite recently the author had recognized why the formula was incorrect. The bifilar law they had assumed was only true for small twists, but he now saw another method of treatment by which he hoped to verify the formula derived from experiment before the next meeting. Prof. Fitzgerald reminded Prof. Perry of a method of attacking the problem suggested by the speaker some time ago, in which each filament was supposed to be wrapped round a smooth cylinder; and said that on working it out the formula was found to be very complicated. Mr. Trotter thought the pairs of strips might be regarded as twisted ladders, and Mr. Gregory said this suggestion reduced the problem to a series of bifilar suspensions which had already been worked out.—On electrifications due to contact of gases and liquids, by Mr. J. Enright. For some time past the author has been studying the electrical phenomena attending solution, by connecting an insulated vessel in which the solution takes place with an electrometer. As a general rule, no effect is observed if nothing leaves the vessel, but when gases are produced and allowed to escape the vessel becomes charged with + or − electricity, depending on the nature of the liquid from which the gas passes into the air. As an example, when zinc is placed in hydrochloric acid, the deflection of the electrometer is in one direction whilst the liquid is chiefly acid, but decreases and reverses as more and more zinc chloride is produced. From such observations the author hopes to obtain some information relating to atomic charges. Owing to the lateness of the hour, the latter portion of the paper and the discussion on it were postponed until next meeting.

PARIS.

Academy of Sciences, Nov. 4.—M. Des Cloizeaux, President, in the chair.—Instrument for measuring the coefficient of elasticity of metals, by Mr. Phillips. This is a large spiral spring and balance wheel, the former made of the metal to be examined.—*Rôle* and mechanism of the local lesion in infectious diseases, by M. Ch. Bouchard. Whereas in absolute immunity, there is, after inoculation, neither general infection nor local lesion, and in total absence of immunity, general infection, often without local lesion, in relative, normal, immunity there is local lesion mostly without general infection; in the last case, as experiment shows, it is not the local lesion that causes the immunity, but *vice versâ*. Inoculating vaccinated and unvaccinated rabbits with pyocyanic Bacillus, the author found, in the former, rapid appearance of leucocytes, all having many Bacteria, which were soon resolved into granulations, and in sixteen hours were quite gone; while the free Bacteria soon decreased in number. In the other animals, few leucocytes, no Bacilli in them, and free Bacteria multiplying.—Statistics of preventive treatment of rabies, from February 9, 1888, to September 15, 1889, at the Pasteur Institute of Rio de Janeiro (Dr. Ferreira dos Santos), by the Emperor of Brazil. Of 156 who underwent full treatment, only one died, and not certainly from rabies; this gives a mortality of 0·64 per cent.—On the velocity of wind at the top of the Eiffel Tower, by M. A. Angot. Three months' observations give a mean of 7·05 m. as compared with 2·24 m. at the Central Meteorological Office (21 m. from the ground). While at low stations there is a minimum at sunrise and a maximum at 1 p.m., the Eiffel (like mountains) showed a minimum about 10 a.m. and a maximum at 11 p.m. (while at midday there was but a slight upward bend of the curve).—On phenyl-thiophene, by M. A. Renard. This is prepared by passing through an iron tube, heated to dark redness, vapours of toluene and of sulphur, and distilling the condensed product. Analysis gave the formula $C_6H_5—C_4H_3S$. With bromine, nitric acid, and sulphuric acid, substitution products are obtained.—Researches on digitaline and tanghinine, by M. Arnaud. By heating digitaline with baryta-water to 180° for several hours, it combines with water yielding the compound $C_{31}H_{52}O_{11}$, from which the formula $C_{31}H_{50}O_{10}$ is deduced for digitaline. The formula of tanghinine, similarly deduced, is $C_{27}H_{40}O_8$. This formula differs from that of Schmiedeberg for digitaline, viz. $C_{21}H_{32}O_7$.—Studies on the embryology of the axolotl, by M. F. Houssay. He describes the mechanics of segmentation, the origin and development of the peripheral nervous system, and the morphology of the head.—On the cytoplasm and the nucleus in Noctiluci, by M. G. Pouchet. Flemming's chromatine seems to be formed of two substances, chromatoplasm and hyaloplasm; and the proportion of the former increases as gemmation proceeds; hence the more and more lively colour of the segmented nuclei.—On the parasitic castration of *Typhlocyba* by a Hymenopterous larva (*Aphelopus melaleucus*, Dalm.), and a Dipterous larva (*Atelenevra spuria*, Meig.), by M. A. Giard. In *T. hippocastani*, the eight terminal branches of the penis are reduced to six, four, or three. A pair of curious invaginations on the ventral surface of the body are also shortened.—Action of serum of diseased or vaccinated animals on pathogenic microbes, by MM. Charrin and Roger. Operating with the pyocyanic Bacillus and rabbits, they found the serum of vaccinated animals more adverse to growth of the Bacillus than normal serum, but somewhat less than that of the diseased animals.—Contribution to the semeiological and pathogenic study of rabies, by M. G. Ferré. Inoculating by trepanation, and with stronger virus than before, they found that the respiratory acceleration appeared on the fourth instead of the fifth day; the respiratory centres being invaded correspondingly sooner. The symptoms could not be attributed to thermal elevation, the maximum of this occurring later.—Statistics of preventive inoculations against yellow fever, by Dr. Domingos Freire. From 1883 to 1889, there were 10,524 persons inoculated in Brazil; and the mortality was 0·4 per cent. The deaths of non-vaccinated during the four epidemics were over 6500.—On the modifications in normal gaseous exchanges of plants by the presence of organic acids, by M. L. Mangin. He injected malic, citric, and tartaric acids into leaves of Japanese prick-wood, bay rose, and lilac, and found these leaves to behave like Cacteæ and Crassulaceæ. In the dark, the volume of carbonic acid liberated is greater than that of oxygen absorbed; and in the light, there is emission of oxygen without correlative absorption of carbonic acid.—On the existence of numerous zeoliths in the gneissic rocks of Upper Ariège, by M. A. Lacroix.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, NOVEMBER 14.

MATHEMATICAL SOCIETY, at 8.—Isoscelian Hexagrams: R. Tucker.—On Euler's φ-Function: H. F. Baker.—On the Extension and Flexure of a Thin Elastic Plate: A. B. Basset, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—On the Lighting of the Melbourne Centennial International Exhibition: K. L. Murray.

FRIDAY, NOVEMBER 15.

PHYSICAL SOCIETY, at 5.—On the Electrification due to the Contact of Gases and Liquids: J. Enright.—On the Effect of Repeated Heating and Cooling on the Electrical Resistance and Temperature Coefficient of Annealed Iron: H. Tomlinson, F.R.S.—Notes on Geometrical Optics, Part II.: Prof. S. P. Thompson.

INSTITUTION OF CIVIL ENGINEERS, at 7.30.—The New Harbour and Breakwater at Boulogne-sur-Mer: S. C. Bailey.

MONDAY, NOVEMBER 18.

ARISTOTELIAN SOCIETY, at 8.—Scepticism: S. Alexander.

TUESDAY, NOVEMBER 19.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Water-Tube Steam-Boilers for Marine Engines: John I. Thornycroft.

ROYAL STATISTICAL SOCIETY, at 7.45.—Opening Address by the President, Dr. T. Graham Balfour, F.R.S.

WEDNESDAY, NOVEMBER 20.

GEOLOGICAL SOCIETY, at 8.—On the Occurrence of the Striped Hyæna in the Tertiary of the Val d'Arno: R. Lydekker.—The Catastrophe of Kantzorik, Armenia: M. F. M. Corpi. Communicated by W. H. Hudleston, F.R.S.—On a New Genus of Siliceous Sponges from the Lower Calcareous Grit of Yorkshire: Dr. J. G. Hinde.

ROYAL METEOROLOGICAL SOCIETY, at 7.—Second Report of the Thunderstorm Committee—Distribution of Thunderstorms over England and Wales, 1871-87: William Marriott.—On the Change of Temperature which accompanies Thunderstorms in Southern England: G. M. Whipple.—Note on the Appearance of St. Elmo's Fire at Walton-on-the-Naze, September 3, 1889: W. H. Dines.—Notes on Cirrus Formation: H. Helm Clayton.—A Comparison between the Jordan and the Campbell-Stokes Sunshine Recorders: F. C. Bayard.—Sunshine: A. B. MacDowall.—On Climatological Observations at Ballyboley, Co. Antrim: Prof. S. A. Hill.

ROCK METAMORPHISM.

Chemical and Physical Studies in the Metamorphism of Rocks, based on the Thesis written for the D.Sc. Degree in the University of London, 1888. By the Rev. A. Irving, D.Sc.Lond., B.A., F.G.S. (London: Longmans, Green, and Co. 1889.)

DR. IRVING is well known as a writer on Bagshot beds. He appears in a new light as the propounder of theories dealing with the metamorphism of rocks. His ideas on this subject are classified under three heads: paramorphism, metatropy, and metataxis. *Paramorphism*, according to the author, includes those changes within in the rock-mass, involving changes in the chemical composition of the original minerals and the formation of new minerals; *metatropy* denotes changes in the physical character of rock-masses; and *metataxis*, mechanical changes, such as the development of cleavage. Changes brought about by the introduction of a new, or the removal of an old mineral (*e.g.* dolomitization) are treated under the head of *hyperphoric change.*

The author writes, he tells us, for those who are willing to look at geological phenomena "in the light of physical and chemical ideas." To all others his dissertation "must read rather like romance than sober science." He is not far wrong when he complains that the chemical side of geology has been neglected since the time of Bischof. The reason for this is to be found in the fact that geologists have been too busily engaged in reaping golden harvests in the demesnes of palæontology and stratigraphy to be much tempted by the allurements of chemical geology. With the resuscitation of petrology, however, the chemical constitution of rocks begins again to present problems of great interest and importance. But the author turns his chemical knowledge to bad account, we think, in applying it to the elaboration of sweeping generalizations. The views he puts forward may or may not be founded on sound chemical and physical axioms; but mere test-tube reactions will not suffice to explain the operations of Nature in the vast laboratory of the universe. The phenomena of metamorphism represent the net result of numerous and often antagonistic forces; and are not always simple reactions that may be expressed by a neat chemical equation.

Dr. Irving appears to be highly gifted with what he terms a "scientific imagination," the meteoric flights of which carry him far above the solid ground of fact or even justifiable theory. An instance of this faculty of the author's will be found on p. 66, where he seeks to explain the origin of foliation in Archæan rocks by the influence of "solar and lunar tides upon the non-consolidated magma in the Archæan and pre-Archæan (*sic*) stages of the earth's evolution." He proceeds:—

"In such an unequally viscous mass there would be tension, contortion, and shearing to any extent during the tidal pulsations which the magma was suffering. . . . Portions already solidified, or nearly so, by segregation or otherwise, as time went on, would by their *vis inertiæ* present obstacles around which a fluxion structure would develop itself in the contiguous portions of the yielding magma, giving us perhaps in some cases 'Augengneiss.' The local tension of parts of the viscous lithosphere, especially near the crests of the waves, would imply stretching and consequent lowering of temperature, a circumstance favourable to local solidification. Who shall say that in the later and feebler struggles of this kind, as secular cooling went on, and the magma approached nearer and nearer to the conditions required for consolidation, some of these tidal waves may not have become *in situ* sufficiently rigid to outline some of the earliest lines of elevation?"

This is speculative enough in all conscience. On p. 29, the author discusses the influence of the salts dissolved in sea-water on submarine lava-flows, and suggests that serpentinization and the conversion of orthoclase into albite are the result of some process of "submarine paramorphism" effected by this agency. This, again, is pure hypothesis, there being no facts to support such a view.

There is a flavour of pedantry in the use of such expressions as "burnt hydrogen" for water (p. 64), or in such sentences as "orthoclase is probably the embryonic silicate of the terrestrial lithosphere" (p. 67). As the old lady is said to have remarked of the word Mesopotamia, there is something especially comforting and satisfying about this last sentence.

The pages bristle with "hard words," some of which are new to science. "Vitreosity" has an uncanny sound; "apophytic" is curious; and "dehydrodevitrification" is as inelegant as it is long. Indeed, so technical is the author's language that a clear understanding of his meaning involves constant reference to his definitions. Unfortunately such reference is rendered impracticable by the absence of an index.

The book bears witness to Dr. Irving's extensive acquaintance with foreign chemical and geological literature; references to foreign sources being abundant, sometimes superfluous. Indeed, there is more evidence of the author's acquaintance with literature than with facts derived from original observation. Good ideas may here and there be picked out; and the work no doubt contains some plausible explanations of geological phenomena; but of this we are assured, that the science of geology will not be advanced by those who spend their time in manufacturing wide-reaching generalizations or attractive theories in the library, but rather by those who are content to labour, with the hammer in the field, the microscope in the cabinet, and the balance in the laboratory at the ofttimes wearisome task of unravelling details.

This book may be placed in the same category as Sterry Hunt's "Chemical and Geological Essays." Such books can be recommended to those with a taste for speculation and rumination. To others they may be productive of mental confusion and headache.

HAND-BOOK OF DESCRIPTIVE AND PRACTICAL ASTRONOMY.

Hand-book of Descriptive and Practical Astronomy. By G. F. Chambers, F.R.A.S. Part I. The Sun, Planets, and Comets. (Oxford: Clarendon Press, 1889.)

THE avowed aim of the author of this work, since the publication of the first edition in 1861, has been to keep its pages up to date—to make it a sort of *vade mecum* to astronomers; and, regarded as a book en-

deavouring to effect a compromise between purely elementary works on astronomy and advanced treatises, it is worthy of some praise. With the many remarkable developments of astronomical science during the last quarter of a century, the bulk of the original volume has been somewhat increased by additions, and it has now been decided henceforth to publish the work in three divisions, viz.—

(1) The sun, planets, and comets.
(2) Instruments and practical astronomy.
(3) The starry heavens.

The first division of the work is now before us, and viewed as a handy book of reference it has many commendable features; but all that could be said in its praise would be the reiteration of comments upon former editions.

The most important application of spectroscopy to astronomy is too well known to need any enlarging upon. It may be said to be almost entirely a creature of the last quarter of a century, but by far the greater amount of this spectroscopic work has been directed to the sun, whilst many new and important discoveries have been made in connection with it. In pre-spectroscopic times a spot on the sun was only that, and nothing more; and a solar prominence was a stupendous flame, the observation of which was only possible at eclipses. Nothing was known of their constitution; and, in fact, all we now know of the physical and chemical condition of the sun has been gained by spectroscopists. However, it is not necessary here to consider the enormous work that has been done in this direction, but it is our duty most emphatically to protest against a compilation such as the one before us—purporting to be a completely revised account of astronomical labours and advances, and yet rendering terribly conspicuous by its absence everything that relates to spectroscopy. It is like a book on locomotion leaving out all about railways because they were not prominent when the first edition was published. The pictorial representations of the corona, the solar prominences, the surface of the sun and the spots upon it, are well discussed in their respective sections, but no room has been given to an examination of their constitution by means of the spectroscope; and indeed, as far as this book is concerned, the whole work that has been done in connection with solar physics might have been left undone.

But these remarks apply not only to the chapters relating to the sun; those on the planets and comets respectively are in the same incomplete condition. Without the spectroscope, the source of luminosity of a comet was far beyond human ken, and its whole constitution was a matter of considerable doubt; with this instrument, however, much has been added to our knowledge—the comet's light has been analyzed, and the whole sequence of changes, as it goes from aphelion to perihelion and back again, is now understood. Yet the spectroscope might never have been turned to these bodies, or indeed utilized in any way, if the utility and importance of the work done were measured by the brief notice with which the author has seen fit to dispose of it, and the following may be said to be the reason for his grievous omissions:—

"The study of the sun has during the last few years taken a remarkable start, owing to the fact that, by the aid of the spectroscope, we have been enabled to obtain much new information about its physical constitution. The subject being, however, a physical rather than an astronomical one, and involving a great amount of optical and chemical details, it cannot conveniently be discussed at length in a purely astronomical treatise, though something will be said concerning it later on in the portion of this work dedicated to spectroscopic matters."

This explanation, however, only aggravates the fault. The importance of the work that has been done is assented to, but, instead of including that part of it relating to the sun in a chapter on that body, instead of considering the spectroscopy of comets as inseparable from a chapter devoted to their discussion, the author has relegated the whole work to an unpublished section devoted to astronomical instruments. Such an arrangement is undoubtedly wrong. A chapter on the sun must contain all that is known about that body, if it strives to be at all complete; similarly, a chapter on comets cannot approach completion unless their spectra are considered; thus this work cannot lead the general public to a just appreciation of the many advancements that have been made. The most elementary text-books rightly include the spectroscopic labours and discoveries, whereas this so-called hand-book, although aiming at being an historical account of the work that has been directed to the sun, planets, and comets respectively, leaves a vast array of facts out of consideration altogether.

There are a few minor faults, one of which is the figure relating to Foucault's pendulum experiment for determining the rotation of the earth. The author appears to have discarded the method of suspension adopted by Foucault, and the pendulum is sketched as if rigidly attached to a beam. The accompanying text also leaves this most important experimental detail out of consideration.

But apart from these points, the work is worthy of some commendation. An addition has been made to the chapter on comets, viz. a method of determining the elements of the orbit of a comet by a graphical process. The catalogue of comets whose orbits have been computed has also been brought up to date, and similar additions have been made to the chapters on periodic and remarkable comets. Doubtless the book will prove to be what it has been heretofore—a handy reference to some astronomical facts.

ELECTRICAL UNDERTAKINGS.

Proceedings of the National Electric Light Association at its Ninth Convention, 1889. Vol. VI. (Boston, Mass., U.S.: Press of *Modern Light and Heat*, 1889.)

WE have before us, in this volume, an account of the proceedings of the National Electric Light Association in the United States during the Convention held at Chicago on certain days in February 1889.

This body is one which, in the United States, has been brought into existence by the growing necessities and rapid expansion of the electric light and power industry. Probably its nearest English analogue is the Iron and Steel Institute. It is essentially a commercial association, and its aims may be said to be comprised within the limits of the exchange of practical information

amongst its members, and of such joint action as will further the use and success of these electrical trades. Hence its objects are not, exactly speaking, scientific, at least in the usual sense of the word, and the intermixture of genuine desire to exchange veritable experience, with a certain element of effort to push into notice particular personal "interests," renders a discriminating mind necessary in dealing with its Reports. At the time of writing, when the work of practically providing London with distributed electric current is being carried on with energy in diverse directions, and the various Electric Supply Companies are laying down mains and establishing stations, this Report serves a useful purpose of enabling us to judge the present state of the industry in the country where, of all others, it has had the most unhindered development.

In his opening address, the President, Mr. S. A. Duncan, gave some figures which are significant of the immense extent to which the electric lighting business has now progressed in the United States. The total number of arc lights in daily use is about 220,000; of incandescent lamps, some 2,500,000. There are approximately 5700 central stations and isolated plants, supplying electric current to single buildings or groups, or sections of towns. There are 53 electric railways in operation, and 44 in progress, on which 378 electric tram-cars travel over 294 miles of track. The total capital employed and sunk in these various undertakings is probably not under fifty millions sterling. When we consider that this is the growth of ten years, we are bound to admit, not only that this youngest of the applied sciences is of vigorous growth, but that its commercial basis must be sound. The Proceedings of the Convention take the form of a series of Reports on various points of interest which are drawn up by individuals or Committees, and then discussed by the whole body.

One of the important questions which in this meeting received consideration was that of underground conductors. It has been evident for a long time that arc-light wires, telephone, telegraph, fire-signal, and incandescent-lamp wires cannot be permitted to increase without limit in the form of overhead conductors. In the early days of the telephone and arc light the inconvenience of overhead wires did not present itself as a formidable one; but, with their rapid growth, the dangers to life and property arising from an indiscriminate collection of electric wires strung on poles or attached to roofs in large cities became apparent. Hence has arisen a demand that they shall be put underground.

Unfortunately this is not so easy in practice as it seems. The distributing companies in many cases desire to avoid the cost of making the exchange in those cases in which they are operating overhead wires. The expense of an underground system of conductors is from five to ten times that of aërial lines. Moreover, the various methods suggested for sub-laying the conductors in streets and roads have all peculiar merits and demerits. Mr. Edison, as is well known, places the copper conductors in steel pipes, insulating them with a bituminous compound, and lays these like gas-pipes in the streets. This system has been operated for years in New York, Milan, Boston, and Chicago, with a high degree of success. Other inventors have advocated a conduit system; others, again, the use of bare copper conductors insulated in a subway. It is thus seen that the necessary experience for satisfactorily laying down underground systems of conductors for the conveyance of large electric currents is only slowly being collected.

The city of Chicago has one of the most completely developed systems of underground conductors for arc-light wires. There are some seventy-eight miles of underground cable conveying currents under a pressure of 1000–1800 volts. The members of the Convention not unnaturally exhibited considerable differences of opinion on this question of underground conductor systems. A Committee appointed for the purpose had issued a circular to about 1066 managers of central stations and lighting systems and others, with the object of eliciting their opinions on the subject of underground conductors. Out of this number 130 returned very full answers to the various questions, and the diversity of opinion seems very great. It is difficult, however, to believe that the process of collecting information was that which would lead to the best results, and although the various views put forward in the discussion on the Report are interesting, they do not indicate a solidarity of opinion on any one point. It is perfectly certain, however, that in England electric conductors for systems of town lighting by electricity will have to be placed underground, and it is also equally certain that those responsible for this work will have to exercise the greatest discretion and take the fullest advantage of existing experience. The question of the fire risks of electric lighting also occupied the attention of the members. In the United States, as with us, the opinion based on experience is that when the work of installing the electric light is carried out under all known proper precautions, and by the best guidance, there is greater safety in it than in gas illumination, but that when these known precautions are disregarded then danger ensues. Minor questions, such as the disruptive discharges in lead cables and fuel oil, attracted briefer attention. The importance of such a gathering in guiding the experience of those who are fostering an industry like that of electric lighting, in which invention advances by leaps and bounds, is very great. We in England, thanks to the revision of the Electric Lighting Act, are now entering on a period of great electrical activity, and already it has been found that the commercial side of electrical engineering requires the association of those engaged in it for mutual advice and joint action, and the London Chamber of Commerce has now an active Electrical Section which fulfils to some extent the functions of the National Electric Light Association in America.

J. A. F.

DIANTHUS.

Enumeratio Specierum Varietatumque Generis Dianthus. Auctore F. N. Williams, F.L.S. Pp. 23. (London: West and Newman, 1889.)

ONE of the things most wanted by species-botanists at the present time is a set of monographs of a number of the familiar large genera of Polypetalous Dicotelydons. The natural orders of Polypetalæ were

monographed by De Candolle in the "Prodromus" between 1824 and 1830, and the scattered material relating to many of the orders and genera has not since been brought together and codified. As instances of genera now involved in great confusion for want of a more recent elaboration, we may cite Ranunculus, Viola, Papaver, Alyssum, Draba, Dianthus, Geranium, Galium, and many others. The present paper is, unfortunately, not a monograph of Dianthus, but only a list of the known species classified into groups, accompanied by general remarks on the structure of the different organs in the genus, and on their range of variation, so that, though it is interesting and useful as far as it goes, it still leaves very much to be desired. Although, on the one hand, Caryophyllaceæ are dried for the herbarium very easily, and suffer little in the process, yet Dianthus is a very difficult genus for botanists to deal with and to understand. There are 230 species for a monographer to characterize. The range of variation between the extreme types is not great, and some of the commoner species (*e.g. D. Seguieri*, *plumarius*, and *Carthusianorum*) are very variable, the consequence being that, one often sees them named in gardens very incorrectly, forms of *plumarius* especially, which is hardy and spreads readily, doing duty for many totally distinct species.

Dianthus is a genus quite characteristic of temperate and sub-temperate climates. It has its head-quarters in Europe and Western Asia. There are several species at the Cape; a few are Himalayan, Chinese, and Japanese; none reach Australia, New Zealand, or the Andes; and only one just touches the extreme north-western tip of the American continent. There are two principal sub-genera: Caryophyllastrum, of which the carnation may be taken as the type, which is far the largest; and Armeriastrum, or Carthusianastrum, of which the flowers are numerous and clustered, as in the sweet-william. There is a third small sub-genus, intermediate between Tunica and the true pinks, which is classified by Bentham and Hooker with Tunica, and by Mr. Williams, following Linnæus and Koch, as a third sub-genus of Dianthus. Within the bounds of the genus, Mr. Williams finds his primary characters—those which mark groups—in the form of the calyx, the nature of the margin of the lamina of the petals, the presence or absence of a beard at the junction of the blade and claw of the petals, filaments, and styles, the shape of the leaf, and the disposition of the flowers; and his secondary characters—those which distinguish species—in the number and shape of the bracts of the epicalyx, the form of the lamina of the petals and their apposition, the character of the calyx-teeth, the form and structure of the capsule, the form and structure of the seeds, and the disposition of the fascicles of veins in the leaves of the barren shoots and flowering stems. His groups and species do not differ materially from those given in his paper in the *Journal of Botany* for 1885, p. 340. The list would have been more useful if he had stated the native country of each species, and added a reference to where it was first described. We hope, however, that he will see his way to publish, before long, the monograph of which this is a mere outline sketch.

J. G. B.

OUR BOOK SHELF.

Magnetism and Electricity. By Arthur W. Poyser, M.A. (London: Longmans, Green, and Co., 1889.)

SINCE the amount of knowledge that is supposed to constitute an elementary scientific education increases every year, there is sufficient justification for the publication of a series of science manuals designed to meet the growing requirements of the Science and Art Department examinations, and this work is an excellent representation of such a series. Apart, however, from the value of this book as an examination manual, it possesses considerable merit. The matter contained in it is just about as much as would cover the course usually taken in a year's school work; the explanatory text is couched in the clearest language, and the experiments described are capable of being easily brought to a successful termination. Also the 235 illustrations will be of considerable assistance to the student, whilst the many exercises and examination questions interspersed throughout the book may be useful tests of his knowledge. The text-books that in their day have been eminently successful, if unrevised, must be supplanted by others which take a more extended view of the subject; hence it is that this book will compare most favourably with any written for the purpose of imparting a rudimentary knowledge of magnetic and electrical phenomena and the laws by which they are governed.

The Engineer's Sketch-book. By Thomas Walter Barber. (London: E. and F. N. Spon, 1889.)

ENGINEERS and draughtsmen generally keep note-books in which are jotted down most things they wish to particularly remember, accompanied by rough sketches when necessary. The author of this book is no exception to the rule. He tells us he has made many notes and sketches during his experience as an engineer, and has often found the want of such a collection for reference. This volume consists of about 1936 sketches, classified under different headings, of devices, appliances, and contrivances of mechanical movements. The book is certainly unique in its way, and will prove useful to those who have machinery to design, who may require suggestive sketches of mechanical combinations to accomplish some desired end. The author truly remarks that a sketch properly executed is to a practical man worth a folio of description. Hence the descriptions given are generally mere names, with occasionally a concise statement of purpose. Each sketch bears a number, and on the opposite page this number is to be found with the description, &c.,—a very good arrangement.

These sketches are clearly printed, and are probably executed from scale drawings in most cases. Taken as a whole, they fairly represent what they profess to do. Sketch 1636, however, is supposed to represent a Ramsbottom safety valve, but it gives a radically wrong impression of this valve. The lever is shown resting on the two valves certainly, but the spring is attached to the lever at a point considerably above the assumed straight line joining the points resting on the valves—an impossible position. Again, one of the two points of the lever resting on the valves is usually loose and connected with the lever by a pin. The sketch shows the lever and the two projecting points made solid. This example is the most unpractical sketch discovered in the book, and should be rectified in a future edition. A fairly good index adds to the usefulness of the volume. There is ample evidence of careful work on the part of the author, and he is to be congratulated on writing a book which will probably be of use to many engineers and those connected with the profession.

N. J. L.

A Life of John Davis. By Clements R. Markham, C.B., F.R.S. (London: George Philip and Son, 1889.)

THIS is the first volume of what promises to be a series of great value and interest. The object of the series, as explained by the editors, is to provide a biographical history of geographical discovery. Each of the great men who "have dared to force their way into the unknown, and so unveiled to us the face of mother earth," will form the subject of a volume; and an attempt will be made, not only to present a vivid picture of the character and adventures of these heroes, but to estimate exactly the scientific value of their work. If the scheme is carried out in a manner worthy of the stirring tales to which it relates, the series will be a source of much wholesome pleasure to all who care to understand how our present knowledge of the earth's surface came to be built up, and who are capable of appreciating the splendid qualities, moral and intellectual, of all who have won for themselves a place in the list of illustrious explorers. The subject of the present volume could not have been intrusted to a more suitable writer than Mr. Clements Markham. He tells in a simple and natural style the tale of Davis's life, displaying at every stage of the story full and accurate knowledge, and summing up clearly the achievements which entitle the discoverer of Davis Straits to be ranked "among the foremost sea-worthies of the glorious reign of Queen Elizabeth." Two admirable chapters are devoted to the following-up of the work of Davis, and in an appendix the author gives all necessary information as to authorities. Mr. Markham has done his work well, and it will be no easy task for the writers of the succeeding volumes to maintain the series at the same high level.

The Brook and its Banks. By the Rev. J. G. Wood. (London: The Religious Tract Society, 1889.)

The Zoo. Second Series. By the Rev. J. G. Wood, (London: Society for Promoting Christian Knowledge, 1889.)

THE first of these two books was written for the *Girls' Own Paper*, and a few chapters of it have been printed in that periodical. Now the complete work is issued separately, and it will no doubt be welcomed by many readers who have already profited by the late author's well-known writings. The reader is supposed to be conducted along the banks of an English brook, and to learn, as he advances, the characteristics of the living creatures which are to be found by the way. The idea is carried out brightly, and—we need scarcely say—with ample knowledge. There are many illustrations, and they add considerably to the interest of the text.

"The Zoo" contains an account of animals of the weasel tribe, the seal tribe, the rodent family, and various kinds of oxen. The descriptions are clear, compact, and lively, and cannot fail to interest the young readers for whose benefit the book was originally planned. Mr. Harrison Weir contributes a number of excellent illustrations.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Protective Coloration of Eggs.

THE following letter records a very interesting observation which is new to me, and I should be glad to hear if any similar fact has been noted before. If not, it would be very interesting if those who have the opportunity would, in the coming spring, seek for as many nests as possible of the red-backed shrike, and see if they can find any correlation between the colours of the eggs and the lining material of the nest.

Parkstone, November 1. ALFRED R. WALLACE.

"*Merchant Taylors' School, Crosby, Liverpool,*
"*October* 15, 1889.

"DEAR SIR,—I wish to bring before your notice an observation of mine relative to the purpose of colour in animals.

"The red-backed shrike (*Lanius collurio*). Colour of eggs—*either* pale blue or green, white ground with zone of spots at larger end; *or, pink ground* with reddish spots.

"*Observation.*—The colour of the lining substance of the nest—such as roots—assimilates to the colour of the eggs, being dirty gray material when the eggs are to be pale (blue or green) white, but being of red-brown roots, &c., when the eggs are to be pink.

"Evidence for above statement. About sixteen years ago I was a lad of fifteen, an enthusiastic birds'-nester, living at Maidstone, and found several (I forget how many) nests, and noticed this; and it so puzzled me—because I could not make out how the bird knew what coloured lining to select, because she made her nest *before* she laid her eggs—that I have never forgotten it. In those days I had never heard of 'The Origin of Species,' nor did I trouble myself about evolutionary theories, knowing nothing about them, so that there was no *predisposing cause* in me to make a wrong observation. Yet I remember it was only a *school-boy's observation*, and therefore it needs confirmation.

"*Assume the fact.* Protective, obviously. Yet, how does the bird know? We know birds build nests from *observing* other nests, and not by instinct wholly.

"(*a*) Have we here incipient species, in which the young, emerging from *pink eggs*, remember their own infancy in a reddish nest?

"(*b*) Has the sight of the red lining an influence over the mother to tinge the eggs pink—*i.e.* would a shrike brought up in a *pink cage* be more likely to lay pink eggs? or a gray rabbit in a black or white hutch have a greater proportion of black or white variants in her litter?

"(*c*) A mere coincidence; too few observations.

"Will you forgive one who intends to be amongst your audience on October 29 and 30, if not prevented, thus trespassing on your time—time which, spent in research, is so valuable to the whole scientific world? Yet, I *do think* my boyhood's observation is worth recording, if only to direct other observers.

"*E.g.* has the amount of white quartzite veins in a cliff, or chalk, *any* influence in the percentage of white, as against blue, eggs of the common guillemot?

"Believe me, yours faithfully,

"(Rev.) FRED. F. GRENSTED."

Science and the India Civil Service Examinations.

THE position of science candidates in the Civil Service competitions is largely in the hands of the science examiners. In some cases they have practically struck their subject out of the schedule by requiring, or by acquiescing in, the demand for a standard of knowledge far beyond the proportion of marks assigned. Even in the last India Civil Service competition the first two men in chemistry only scored 196 and 195 respectively, whilst the first two in German, out of the same maximum, gained 359 and 353. If the eminent men of science who undertake these examinations would see that science had fair play, many more candidates would be encouraged to study it. Whatever the private views of the Civil Service Commissioners may be, their absolute justice and honourable impartiality are unassailable. Even if they did not altogether concur in the opinions of the examiners, they would give their arguments careful consideration, and see that all interests should be duly regarded.

It will not advance the claims of science to weight them with the very doubtful proposition that "the Universities of England and India" are the only places where "well educated" men are to be found. Many most distinguished men of science have not had the advantage of a University degree in early life. No one would venture to class them for this reason in "an inferior order of men." HENRY PALIN GURNEY.

2 Powis Square, W., November 15.

The Physics of the Sub-oceanic Crust.

In the new edition of his "Physics of the Earth's Crust," Mr. Fisher has made a great advance on his former position, for he sees his way to explain the formation of mountain chains, and all the phenomena of compression which are so strikingly exhibited in the crust of the earth, without depending on his former theory of columnar expansion, and without falling back on the contraction hypothesis.

He believes that the existence of a liquid substratum beneath a thin crust is consistent with the physical conditions of the universe; and argues that no appreciable tide would be produced in it if the liquid magma consisted of an intimate association of fused rock and dissolved gases. He further concludes that this magma is not an inert or motionless liquid, but one in which convection currents are constantly bringing up heat from below, and leading to frequent internal displacements of mass.

In this hypothesis he finds a means of explaining the movements of the earth's crust. Whether Mr. Fisher's position can be maintained must be decided by those who are accustomed to deal with the physical problems involved, but geologists will be glad if it should prove that the objections to the existence of a liquid substratum have been successfully met, for they have always found a difficulty in explaining geological phenomena without having recourse to the supposition of a liquid layer.

One of the most important chapters in the book is that on the sub-oceanic crust, and it is on this that I propose to offer a few remarks, taking it for granted that a truly liquid substratum with a play of convection currents does really exist.

Mr. Fisher's object is to ascertain the thickness and density of those parts of the crust which lie beneath the oceans, and to see whether in these respects they differ from the continental portions. This he does by making a series of assumptions, and considering how far the results are compatible with known facts and conditions. This process involves the dismissal of certain hypotheses, but although he eventually finds one which fulfils the requisite conditions, it does not follow that no other equally satisfactory hypothesis can be found. Consequently his results though interesting cannot be regarded as final. The suppositions he is obliged to introduce before obtaining satisfactory results are, that the density of the subtratum beneath the continental and the sub-oceanic portions of the crust is different, and that the sub-oceanic crust consists of two layers of different densities.

It is conceivable, however, that the lower part of the crust is *everywhere* denser than the upper part, and consequently that two layers of continental crust should be introduced into the problem; whether this hypothesis would likewise fulfil the conditions, and whether it would lead to the same results as that which Mr. Fisher adopts, could only be ascertained by trial. Mr. Fisher informs me that he has not made this trial, and that every additional assumption introduced increases the great labour of the calculations.

Let us assume, however, that no other hypothesis would satisfy the conditions so well as that which he has adopted, and let us see to what conclusions it leads. Mr. Fisher derives from it the following important results:—

(1) That the sub-oceanic crust dips more deeply into the substratum than the continental crust.

(2) That its lower part is more dense than the substratum.

(3) That the density of the liquid substratum is less beneath the oceans than beneath the continents.

This last result leads to the conclusion that the differences of density in the substratum must give rise to ascending and descending convection currents, and that the ascending currents will rise beneath the oceans while the descending currents will occur beneath the continents. "That the former occupy so much larger an area is," he says, "no more than we might expect, because to whatever immediate cause they may be due, they are ultimately the result of secular cooling. . . . The descending being merely return currents will be confined to the smaller area, but on that account they will move the more rapidly."

Finally he says that these conclusions confirm the theory of the permanence of oceans, "because it is difficult to conceive how the subjacent crust, once more dense, can have subsequently passed into the less dense condition which would be requisite to render it continental." I venture to think he is hardly justified in making this unqualified statement, and purpose to show that his results only confirm the theory of the permanence of oceans in a limited and partial manner.

In the first place, if chapters xvii. and xxiv. are read carefully, it will be obvious that Mr. Fisher uses the terms oceanic and sub-oceanic in a special sense. On p. 233 he classes areas having less than two vertical miles of water as "extensions of the elevations that produced the continents," and even those with depths of two to three miles of water he regards as "sometimes connected with and prolongations of the first." In other words, he looks upon the shallower parts of the great oceans from a continental coast-line to a depth of at least 2000 fathoms as extensions of the continental elevations.

Again, on p. 331 we find him saying that New Caledonia and the Seychelles are not properly speaking oceanic islands, because the first is a prolongation of the submerged ridge which connects New Zealand with North Australia, and because the latter belongs to an extension of the Madagascar ridge into the Indian Ocean. Now a reference to the physical chart of the oceans given in the "Narrative of the Cruise of the *Challenger*" (vol. i.) shows that the 1000-fathom line completely encircles New Caledonia and the adjacent islands, and that the submerged ridge which he speaks of would be a very narrow one unless we regard it as extending to the line of 2000 fathoms; but this line includes also the Solomon Islands, the Fijis, and the Friendy Islands, so that if New Caledonia cannot be considered as an oceanic island neither can the other islands just mentioned, though no one would reject them from that category on other grounds. Similarly, the Seychelles and Amirantes are surrounded by water of more than 1000 fathoms, and are usually regarded as oceanic islands. The same may be said of Barbados, where stratified Neozoic rocks are found.

The contour-line of 1000 fathoms has, I think, been generally taken by recent writers as the approximate limit of the continental elevations, the space outside this being regarded as oceanic; the islands which rise from depths of over 1000 fathoms would on this view be necessarily classed as oceanic, and as a matter of fact all such islands come within the terms of Sir A. Wallace's definition of an oceanic island except that a few of them are not entirely of volcanic or coralline composition. To exclude all the islands which rise from within the 2000-fathom limit would necessitate the division of oceanic islands into two classes, the definition of which would be difficult.

I am not saying that such a distinction would be incorrect, or that Mr. Fisher has no right to assign larger limits to the continental elevations and narrower limits to the oceans: I only desire to show that he takes a special view, and that he declines to regard islands which rise from less than 2000 fathoms as specimens of the sub-oceanic crust. His discussion of the probable structure of the *sub-oceanic* crust deals therefore with areas which are covered by water of three miles or more in depth—that is to say, from about 2500 to 5000 fathoms, and the comparison which he makes between patches of sub-continental and sub-oceanic crust is really between a piece of continental land and a piece below an area of deep ocean at a considerable distance from the continents.

With regard to this point, I have had the advantage of a further explanation from Mr. Fisher; writing to me he says:—"My sub-oceanic patch may be anywhere under the ocean, but you must remember that all the quantities are subject to change except c, ρ, μ, σ, as δ diminishes; *i.e.* as the ocean grows shallower toward the coast-lines, the thicknesses and densities merge into those at the sea-level, the second layer of the sub-oceanic crust at the same time thinning away to nothing. You are quite right in thinking that in a general way in discussing the sub-oceanic crust I am dealing with the crust at a considerable distance from the continents. . . . . I do not profess to explain the structure of the crust of the earth in those parts which appear to have sometimes been land and sometimes sea. I should, however, guess that having been at times land the crust there resembles the present continental crust. Still the equations (p. 242) must apply to these parts if only we knew what assumptions to make."

Since, therefore, there are regions of sub-oceanic crust the structure of which may resemble that of the continental crust rather than that beneath the central parts of the oceans, it is clearly of importance to consider the position and extent of these regions. Let us first take that part of the Pacific Ocean in which New Caledonia is situate; if we are to regard it as a submerged plateau which may once have been continental land, it acquires a special interest. The contour of 2000 fathoms which unites New Caledonia to Australia and New Zealand extends from the north coast of New Guinea by the Solomon Islands to Samoa, and then bends southward to New Zealand, but curves out again

so as to include the Chatham and Antipodes Islands, some 600 miles to the south-east of New Zealand. Southward it has a connection with the Antarctic continent, but a deep gulf of over 2000 fathoms runs far up outside the east coast of Australia. The area within the 2000-fathom line measures about 2500 miles across its northern portion, and has an extreme length of about 3600 miles from its northern border to the south end of New Zealand.

If this large area is not to be regarded as strictly oceanic—that is to say, if the physical structure of the crust beneath it differs from that of the crust beneath the deeper ocean outside it—and if its geological history is different from that of this deeper oceanic area, and is comparable with that of a continent, then a very important modification is introduced into the theory of the permanence of oceans and continents.

We learn that an area now covered with oceanic deposits may not have been always ocean, and this is precisely what Lyell and his followers have always maintained; for if so large a part of the Pacific may have been land (say in the Cretaceous period), there has been what most geologists would consider to be a change from continental to oceanic conditions; and if, being such a transmutable region, it may eventually be raised again till large parts of it become land surfaces, round which shallow water deposits could be formed, it would exhibit strata of deep-sea origin (usually called oceanic) intercalated between formations of the ordinary continental type.

Another region where similar transmutations appear to have taken place is that of the West Indian Islands with the adjoining area of the Caribbean Sea and a portion of the Western Atlantic. Of this region the structure of Barbados is an illustration. That island conforms to the ordinary definition of an oceanic island; it is separated from South America and the rest of the Antilles by water of over 1000 fathoms, and the scanty fauna which it possesses is not such as would have been introduced by any former land connection. Its geological structure is simple but striking: there are no volcanic rocks, but a basal series of sandstones and clays that are similar to the older Tertiaries of Trinidad, and may be regarded as testifying to a former northern extension of the South American continent; above these are oceanic deposits, consolidated radiolarian and foraminiferal oozes, which appear to be of very late Tertiary age (Pliocene or Pleistocene). Capping the whole are raised coral reefs. Here, therefore, is part of a continental (or shallow sea) area which has sunk into oceanic depths during the Tertiary period, has received a burden of oceanic deposits, and has risen again to be invested with a formation of essentially shallow water origin. Certainly geologists have no proof of greater geographical changes than this, though Europe affords evidence of quite as great a change, for in the area of the European chalk we have an instance of similar oceanic conditions to those under which the Barbados earths were deposited; yet this area was continental land before the Cretaceous period, and has again become so since that period.

The other oceanic areas which have less than 2000 fathoms of water over them are the Arctic Ocean, the southern part of the Indian Ocean, and part of the North Pacific between America and Kamchatka. It would appear then that we may claim these regions, together with the Caribbean area and a large part of the Western Pacific, as areas which have been interchangeable with the present continental surfaces.[1]

Mr. Fisher does not discuss the subterranean structure of the shallow ocean areas, but in his letter already quoted he inclines to think that the crust beneath them is similar to the continental crust, and this view is borne out by the structure of certain oceanic islands; but though the density and general structure of the crust may be similar to that of the continents, the condition of the liquid substratum may not be exactly the same, or rather there may be differences in the force and direction of the convection currents which traverse the substratum.

In chapter xxiv. Mr. Fisher does briefly consider the condition of the substratum in the tracts that lie between the continents and the [deep] oceanic regions. Having shown that, if the density of the substratum is less beneath the ocean than beneath the land, the convection currents must rise beneath the oceans and descend beneath the continents, he points out that there must be a certain space between the lines of ascent and descent where the currents will move more or less horizontally. In this horizontal movement he finds a force capable of exerting strong pressure on the continental crust. Now in some parts of the world the space along which these horizontal currents move may be narrow, but in others it is probably broad: thus, on the east side of the Pacific, where the change from ocean depths to mountain heights is rapid, this space is doubtless small, but on the west side of the same ocean, as we have seen, there is a broad intervening area of shallow ocean, and beneath this the currents that move westward may continue to be mainly horizontal till they reach Australia.

The behaviour of convection currents is so little understood that one cannot predicate much about them; there would probably be a certain play of ascending and descending currents beneath the broad semi-oceanic area as well as horizontal currents, and very slight changes may cause these to vary in volume and to alter their positions; such a region is therefore likely to be in a state of unstable equilibrium, and its upheaval or further subsidence would depend on the balance that is established between the three sets of currents in the liquid substratum beneath it.

Another question suggests itself—namely, whether the oceans have always been as deep as they are now. According to Mr. Fisher's results, the mass of the sub-oceanic crust is greater than that of the sub-continental crust, but he gives reasons for thinking that its thickness is not greater, and if this is so, then its density must be greater; and it is from this he deduces the permanency of the oceans, because it is difficult to conceive of the denser crust becoming less dense, which would be necessary before any part of it could be converted into a continent. But though this difficulty certainly exists, it does not preclude the possibility of the sub-oceanic crust having been originally less dense than it is now; it may have been growing denser, and there may have been a corresponding increase in the size and depth of the oceans at the expense of the continents. His results, in fact, do not involve the permanency of the present continents, or of the present relative proportions of land and water surfaces. We are at liberty to imagine a time when there was much more land than there is at present, and when all the oceans were comparatively shallow; there being at this early period less difference in the comparative density of the sub-oceanic and sub-continental crust.

We may, in fact, postulate a secular increase in the size of the oceans and in the depth of the ocean basins corresponding to a secular increase in the density of the sub-oceanic crust; and possibly as a consequence a general increased stability of the whole crust.

The supposition of a secular increase in the depth of the oceans is in accordance with the evidence of geological history, for if there had been such an increase we should expect to find that oceanic deposits of the modern type were essentially Neozoic formations, and would not occur among Palæozoic rocks; and such appears to be the case. At present we do not know of the existence of any purely oceanic limestone that is older than the Cretaceous period; and among the Palæozoic rocks there are none which appear to have been formed at any great distance from continental land.

I think it has now been shown that Mr. Fisher's conclusions do not give unqualified support to the theory of the permanence of oceans, but that, on the contrary, they are consistent with two important limitations of the theory—limitations which had already been suggested by geologists before the publication of Mr. Fisher's book. Thus, Prof. Prestwich has expressed the opinion[1] "that it is only the deeper parts of the great ocean-troughs that can claim the high antiquity which is now advocated for them by many eminent American and English geologists"; and I have suggested the probability that "the tendency of all recent geographical changes has been to deepen the ocean-basins, and to raise the mountain-peaks to higher and higher elevations."[2]

It is therefore satisfactory to find that the results of purely physical and mathematical reasoning, on the one hand, and of a consideration of the geological evidence, on the other hand, are so closely in accord. The importance of this agreement consists in the way it opens for the reconciliation of two opposing geological schools: an important limitation is imposed on the Lyellian belief in the past interchange of oceanic and continental areas; while the extreme view, held by Dana and others, that there has been no such interchange at all, may be equally far from the truth; the probability being that truth lies midway between the two extremes.

It is also worthy of note that the hypothesis of a secular increase in the depth of the oceans and the heights of the moun-

[1] The ridges in the Central and Southern Atlantic do not come within the category of shallow oceans.

[1] "Geology," vol. ii. p. 547.

[2] "The Building of the British Isles," p. 334.

tains brings the whole succession of past geological changes within the scope of a general theory of geographical evolution.

A. J. JUKES-BROWNE.

The Composition of the Chemical Elements.

MY excuse for troubling your readers with this well-worn theme is that a definite hypothesis is possible, which, should it be fully borne out by the facts, appears to afford a remarkably complete explanation of the periodic law, as set forth in Prof. Mendeleeff's table.

The periodicity exhibited by this table is double, alternate series presenting members which have high or low atomic volumes, are fusible or infusible, &c.

Should the elements be really simple atoms, it would be impossible to account for this fact without introducing occult differences of quality, from which it has been all along the aim of chemical science to free itself. Undoubtedly periodical variations in the size and shape of the atoms might account for the dual periodicity of their properties, but nothing satisfactory can be gleaned from such an explanation. Besides, we are accustomed to regard differences of properties in compounds as dependent on composition, even should their molecular weights be similar. It may also be urged that, if the elements are supposed single, their properties should vary with increase of weight in some continuous manner, and not sway to and fro so remarkably. I am aware that Prof. Mendeleeff himself does not take this view (cf. Chem. Soc. Journ., October 1889), but it is one that is widely spread, and is held by other eminent chemists.

It is, however, possible to push too far such analogies as that of a series of organic compounds. Important differences exist between such a series and that of a natural family of the elements: for example, the specific refraction equivalents are not at all analogous in the two cases. Specific heat determinations show that, as a rule, an element moves as a single solid mass. But these considerations need prove nothing more than that we must be prepared to deal, in the case of the elements, with affinities of a different order—perhaps brought into play by vastly different conditions—from those found in ordinary compounds.

If the elements are assumed to be composite radicles, then, in stating their hypothetical composition, there is material ready to hand. The famous principle known as "Occam's razor" applies here as elsewhere. Hypothetical elements should only be introduced where other considerations are plainly in favour of the suppositions involved.

The elements form natural families of two groups each, six of them having for their types the following: Li, Be, B, C, N, and O.

Since the properties of the typical element run all through the members of a family, then (on the hypothesis that properties depend upon composition) we should expect it to be found in the formulæ of the remainder.

The hypothesis here advanced is, that the periodicity of the properties of the elements is due to the dependence of the properties of each element upon those of the typical element of the family to which it belongs, together with the mode of its combination with oxygen. In other words, that the elements, with the exception of the first six, are, in a qualified sense, compound oxygen radicles.

The reasons for the adoption of oxygen are: (1) the remarkable coincidence of the figures for each family upon this hypothesis; (2) that the atomic weights of the oxygen family of elements are whole multiples of that of oxygen; (3) the relations disclosed between the numbers of atoms composing the elements, which cannot be other than the result of law; and (4) the fact that all the elements combine with oxygen, which is also the most plentiful element in Nature.

Supposing any natural family complete, its two groups are given by the following formulæ, R being its typical element:—

$$R \begin{cases} \text{Group } (a): RO_2,\ RO_5,\ RO_8,\ RO_{11},\ RO_{14}. \\ \text{Group } (b): RO,\ R_2O_3,\ R_2O_6,\ R_2O_9,\ R_2O_{12}. \end{cases}$$

The seventh and eighth families are very incomplete, but may be represented in the same way.

It will be noted that the numbers of atoms in these formulæ are as follow:—

$$\begin{cases} 3,\ 6,\ 9,\ 12,\ 15. \\ 2,\ 5,\ 8,\ 11,\ 14. \end{cases}$$

The common difference in each group being 3, and the numbers 4, 7, 10, and 13 being absent.

The resemblance of these figures to the atomic weights of the ten typical elements (including four hypothetical ones) is very close. One is almost tempted to regard them as the primitive forms of the combination of matter, and to return to Prout's hypothesis.

The existence of *four* elements between H and Li is indicated as well by the gap which exists between them as by this hypothesis. That Fe, Co, Ni, &c., have formulæ commencing with R_2, is shown by the fact that they recur regularly in the series having these formulæ, their comparative infusibility and low atomic volume indicating also this composition, as well as the fact that, if it were otherwise, the rule observable in the first six families would be broken through. It is, again, hardly possible to suppose that the seventh family, the halogens, should contain the electropositive hydrogen, although the latter would then lose its unique position, and in this case the *difference* between the calculated values of Ag and I (18·9) agrees very nearly with that between those observed (18·87), the *ratio* of these latter being very exactly determined by Stas. This, however, is a matter which may well be left undecided for the present. Should fluorine be a fundamental element, the halogen series will break the rule which holds for at least six out of the remaining seven families.

The following table is constructed on the lines of Mendeleeff's. The seventh and eighth families are placed first in order, and the calculated and observed atomic weights are placed underneath their respective formulæ. Want of data is indicated by blanks, but the rarer metals are omitted, although they mostly correspond to the formulæ R_2O_9. It will be noted that the arrangement gives Mn, Fe, Co, Ni, and Cu an intelligible position in the series.

It is not to be expected that the calculated and observed figures will perfectly agree, although in some thirty cases the average variation is 0·5 of a unit. The chief variations occur in two series, in which, however, the natural order is preserved, viz. Ti, V, and Cr, with an average error of 4·5, and all the elements containing O_{12}, from tungsten to bismuth, in which the mean difference is 9. It will be noted that this difference holds even in the case of the eighth family, in which the formulæ contain the hypothetical R^{ii}, R^{iii}, and R^{iv}, showing that the errors arise from a common cause. The atomic weights, since the discovery of the periodic law, have not been decided upon without reference to one another. This whole series is separated by a huge gap from the rest of the atomic weights, which is only filled in at intervals by the less common metals of the earths, &c., and consequently an error in one of them would certainly affect the whole. Similarly, the differences of 4 between the observed atomic weights of Ca and Sc, and Sc and Ti, are anomalous.

On the other hand, the coincidences exhibited by the table cannot be the work of chance, and, considering the inexactitude of the determinations of many of the atomic weights, the fact that the average of the differences between the observed and calculated numbers in the large majority of the elements is only one unit, and that the remainder appear to arise from a single cause, is remarkable, especially when we consider the facts which are brought to light by this mode of representation. The law that elements essentially similar differ only by an atomic weight of O_3, or its multiple, surely deserves attention. When, again, the difference between the two groups of any natural family, and the periodicity of the properties of the elements, are exhibited as the result of composition, the conclusion becomes apparent that we have in the hypothesis at least a guide for future research.

The atomic volumes of the groups commencing with RO are smaller than in those commencing with RO_2. These correspond to the "even" and "odd" series of Mendeleeff. Other properties follow, thus affording a possible clue as to *how* the characteristics of the elements depend upon their composition.

Without trespassing further upon your valuable space, I will conclude by quoting Dr. Gladstone (Pres. Address, Chemical Section, Brit. Assoc., Southport, 1883):—

"The remarkable relations between the atomic weights of the elements and many peculiarities of their grouping, force upon us the conviction that they are not separate bodies created without reference to one another, but that they have been originally fashioned, or built up from one another, upon some general plan. This plan we may hope to understand better; but if we are ever to transform one of these supposed elements into another, or to split up one of them into two or three dissimilar forms of matter, it will probably be by the application of some method of analysis hitherto unknown."

Mirion Terrace, Crewe, October 25.

A. M. STAPLEY.

Is Greenland our Arctic Ice Cap?

THE result of Dr. Nansen's journey across Greenland, establishing, as it practically does, that this Arctic continent is covered by a huge ice cap, promises to be a matter of some interest in several ways.

Among other things it may possibly yield a clue as to the cause of the south polar cap of Mars being so very excentrically placed.

Since the time of the elder Herschel this has been a subject of speculation, and various ingenious suggestions have been put forward by astronomers to account for the presumed anomaly.

Webb, in his "Celestial Objects," p. 147, tells us that Herschel found that the caps were not opposite each other; and says himself that "one would expect that they might have been diametrically opposite."

"Mädler and Secchi found the north zone concentric with the axis, but the south considerably excentric"; and "it has been suggested by Beer and Mädler that the poles of cold may not coincide with the poles of rotation."

Later on, at p. 148, he tells us that "Secchi found the appearances at the poles irreconcilable with the idea of circular caps, and was forced to adopt the supposition of complicated and lobate forms. Schiaparelli alludes to the possibility of a mass of *floating ice*."

Apparently it was taken for granted that the *ice* or snow caps of Mars, should not only be truly circular in form, but centrally placed over the axis of rotation, like the cloud caps of Jupiter and Saturn.

But it seems to me that Dr. Nansen's journey will go a long way towards solving this problem, by demonstrating that Greenland is practically one of our two polar ice caps. On our South Pole we have one, more or less centrally placed over the axis of rotation, and which certainly does not float about, having two large active volcanoes on it. It corresponds fairly well to the northern pole of Mars. But on our North Pole—as far as we can see—there is no large permanent ice cap, and in its place we have an irregular, extensive polar basin.

Roughly speaking, we may say that the character of the Arctic and Antarctic ice bears this out, for in the south we see the immense flat-topped bergs of 2000 feet thickness, and several miles long, which are obviously portions of the southern ice cap broken adrift. In the north we see a preponderance of floe, or thin field-ice, a few flat-topped bergs near Franz Joseph Land (Young), and the angular bergs of the Atlantic, mainly from West Greenland (Greely).

If our Arctic basin is deep and has few islands in it, it stands to reason that a permanant ice cap could not form, or become anchored, there; the floe would be perpetually broken up by storms and tides, carried away, and melted. A floating ice cap would be impossible. The presence of a polar continent—even excentrically placed—would seem to be necessary, as in the case of Greenland. This would indicate the solution for the supposed anomaly, *re* the position, of the south polar cap of Mars, and for the lobate appearances remarked by Secchi in 1858.

If the foregoing remarks are at all likely to be correct, Dr. Nansen's journey may have quite unexpectedly solved for us an interesting astronomical problem, and thereby afforded another clue to the condition of Mars, a proof almost of partial glaciation.

I believe that M. Fizeau regards the so-called "canals" as evidence of the "movement and rupture" of a glacial crust.

But if this crust is formed on, and attached to, any extensive *land* surface (such as Greenland, say), it is not easy to account for such enormous ruptures, and the lateral movement.

If the canals are looked on as huge lanes of open water in a floating ice-pack, they would vary in size and form almost daily.

Sibsagar, Assam, India, September 25. S. E. PEAL.

Globular and other Forms of Lightning.

MR. A. T. HARE's account in NATURE, vol. xl. p. 415, of a flash of globular lightning seems to illustrate so well the explanation which I gave, many years ago, of the formation of fire-ball lightning, that the following extract from my pamphlet "On Atmospheric Electricity" (London, Hardwicke, Piccadilly, 1863) and the remarks which I have appended to it, may perhaps not be without interest at the present time. The pamphlet is not now on sale. The quotation is from pp. 45-46; I omit a few references:—

"A slip of tin-foil was formed into a hollow cylinder, and thrust tightly into one end of a glass tube which was about $\frac{7}{16}$ inch in external diameter, and the glass was not very thick. A brass ball was fixed to the end of the glass tube, and the tin-foil extended from the ball to the distance of about $12\frac{1}{2}$ inches from it, and all the tin-foil was inside the glass tube. The remainder of the glass tube served for an insulating support to the part which held the tin-foil. On electrifying the ball, the electricity is conveyed by the tin-foil to the inside surface of the lined part of the glass tube; and at the same moment the outside of this part of the tube is electrified inductively, and with the same sort of electricity as that with which the interior of the tube is charged. The part of the tube which held the tin-foil was supported horizontally. There was also a copper hook which could be set on any part of the outside of the lined portion of the glass tube.

"The copper hook was set at a distance of $7\frac{1}{2}$ inches from the brass ball on the end of the tube, and was connected with the outside of a Leyden-jar which was charged so as to be nearly able to give a spark $\frac{1}{2}$ inch long between two other brass balls each of which was $1\frac{1}{4}$ inch in diameter. The knob of the jar was next brought to the ball on the end of the glass tube; the discharge readily passed over the $7\frac{1}{2}$ inches of the electrified outer surface of the glass tube. Sometimes the spark could pass when the hook was at $8\frac{1}{2}$ inches from the ball. When the hook was placed at a distance of $12\frac{3}{4}$ inches from the ball, the spark passed between the ball and the hook with a much lower charge in the jar than was necessary to produce a spark $\frac{3}{8}$ inch long between the pair of balls before mentioned.

"These experiments show that the length of an ordinary electric spark, can be much increased by causing the spark to pass over an electrified surface. Instances of this are seen in the spontaneous discharge of Leyden-jars, and in the long sparks which flash over the revolving glass of the electrical machine.

"Let a ball be attached to the prime conductor of the electrical machine so that the ball may give electrical brushes to the air. Much longer sparks may be drawn from the ball along the path of the brushes than from the other parts of the prime conductor. The brush discharge electrifies the air in the neighbourhood of the ball, and the spark is longer because it passes near to, or through, a mass of previously charged particles.

"It is well known that atmospheric electricity not unfrequently forms an electric fire-ball which moves but slowly, and which, on striking an object, explodes and produces all the usual effects of a flash of lightning. Sir William Harris writes:— 'Now, it is not improbable that, in many cases in which distinct balls of fire of sensible duration have been perceived, the appearance has resulted from the species of brush or glow discharge already described, and which may often precede the main shock.' And Dr. Noad says of the electrical fire-ball that 'it is no doubt always attended by a diffusely-luminous track; this may, however, be completely eclipsed in the mind of the observer by the great concentration and density of the discharge in the points immediately through which it continues to force its way.' A more perfect explanation can, as I suppose, be given by the aid of the experiments of this chapter.

"A thunder-cloud may produce both the electric glow and the electric brush, at the end of one of its cloudy branches. And since electricity passes freely along a charged surface, therefore the glowing discharge by electrifying the air in front of the aërial conductor, adds continually to the length of the conducting column, and so the electrical fire-ball advances. Little drops of water, or any other conductive matter which the column finds in its course, must facilitate the transmission of the electricity to the fire-ball; and without doubt, too, the electricity of the column continues to spread laterally, and so it increases the conductive capacity of the column. The electricicity travels through the electrified column as a series of luminous disruptive discharges; but the light is brightest at the head, because there the diameter of the column is least, and the discharge is most closely packed; and because there the air is unelectrified, and consequently opposes so great resistance to the passage of the electricity. As soon as the fire-ball has arrived at a conducting mass on the earth, the aërial conductor has been completed, and a flash of lightning may instantly follow along the path of the fire-ball."

Since the Leyden-jar, with a charge somewhat less than that required to give a spark $\frac{1}{2}$ inch long between the $1\frac{1}{4}$-inch brass

balls, gave a spark about 8 inches long over the excited glass tube; and since the Leyden-jar, with a charge much lower than that required to produce a spark $\frac{5}{8}$ inch long between the two brass balls, was sufficient to give a spark about 13 inches long over the excited glass tube; it was at once seen that the length of the spark over the excited glass tube, increases faster than the intensity of the charge of the Leyden-jar. Of course the law which connects the length of the spark over the excited glass tube, with the intensity of the charge of the Leyden-jar, can only be determined by experiment. It is, however, to be noticed that, from the experiments of Harris and others, the length of a spark in air of a Leyden-jar varies directly with the intensity of the charge—that is, with the quantity of electricity in the jar as measured by any such contrivance as the unit-jar. And further, that the length of the spark over the excited glass tube depends (1) on the length of the spark which the charge of the Leyden-jar can produce between the $1\frac{1}{4}$-inch brass balls; and also (2) on the degree of electrification of the glass tube; and that both these two quantities—namely, (1) and (2)—increase together. From these considerations, I should expect to find that the length of the spark over the excited glass tube increases in some way with the square of the intensity of the charge of the Leyden-jar—that is, with the square of the potential.

I dare say that the sparks over the excited glass tube, would become very brilliant by using an induction coil to charge the Leyden-jar. But to produce the maximum effect, the glass tube should, I think, be lined, as in the following experiment, with tin-filings instead of the tin-foil.

A piece of hard German glass tube was taken, and one end closed at the blow-pipe and the other end bordered to receive a cork. After these operations, the tube was found to be just 2 feet $2\frac{3}{8}$ inches long; the external diameter of the tube was $\frac{11}{16}$ inch, and the glass was $\frac{1}{20}$ inch thick. Next, the closed end of the tube was filled with tin-filings to the height of 6 inches. [illegible] by tapping the end of the tube [illegible]ce of wood. A brass rod, with a knob at one end [illegible] a screw having been cut on the other end, was screwed into a cork which nicely fitted into the glass tube, and, by means of the rod, the cork was thrust into the tube until it pressed upon the tin-filings, and since the point of the rod was sharp and projected beyond the cork, the end of the rod entered a little way into the tin-filings. The knob of the brass rod now stood just at the mouth of the glass tube, and the mouth of the tube also contained a cork through which the brass rod passed. Of the outside of the glass tube, the part surrounding the tin-filings was painted over with lac varnish, and, as soon as it became sufficiently sticky, a thin piece of tin-foil was wrapped around the tube so as to cover the tin-filings, and no more. Lastly, the remaining portion of the outside of the glass tube was painted over with lac varnish. To charge this tubular Leyden-jar, it was laid with the tinned end on one conductor and with the knob of the brass rod on the other conductor of a Wimshurst influence machine. I may mention, in passing, that the capacity of this tubular Leyden-jar was surprisingly great in comparison with its size; thus showing that Leyden batteries, both cheap and compact, can be made with the aid of glass tube and metallic filings. The capacity is no doubt due, more or less, to the uniform thinness of the glass, and to the close contact of the tin-filings and the glass. The specific inductive capacity of hard German glass does not seem to have been ascertained. But of course, for the construction of Leyden-jars, and also for the plates of the Wimshurst machine, glass of the highest available specific inductive capacity should be used. It may not be amiss to remark that, owing to the high specific inductive capacity of glass as compared with air, the efficiency of a Wimshurst machine is probably much more increased by diminishing the thickness of the stratum of air between the glass plates than by diminishing the thickness of the plates.

Now, the Leyden-tube produces a class of sparks which I do not think have been shown by any other Leyden-jar. The Leyden-tube was laid, as before mentioned, on the two conductors of a Wimshurst influence machine, and the discharging balls belonging to the conductors were set $\frac{1}{2}$ inch apart. These two discharging balls were each $1\frac{3}{4}$ inch in diameter. On turning the handle of the machine, the Leyden-tube continued, of course, to become charged and then to be discharged by the $\frac{1}{2}$-inch spark between the discharging balls. But besides the the tin-foil to a distance of $1\frac{1}{2}$ inch or more. These sparks were, I think, best seen in a subdued daylight. They were very numerous with each discharge of the tube; I estimated the number of sparks in different discharges as varying between one and two dozens. The sparks were sinuous, very bright at the tin-foil, and tapering away to nothing at the further end. Some of the sparks, however, were not so bright as the others, and rather ruddy; they were probably inside the glass tube, and coloured by the varnish on the tube.

In the *Leisure Hour*, November 1888, p. 777 (56 Paternoster Row), there is a photographic picture of a lightning-blaze, wherein the bright ends of several of the flashes are seen to be sitting upon what appears to be rock, and the flashes bear a strong resemblance to the little sparks whose bright bases rest upon the edge of the tin-foil.

In the *Leisure Hour*, November 1886, p. 786, there is another representation of a flash of lightning from a photograph. In this instance, the flash is thick in the middle, but on approaching the earth, it tapers off to a fine point. Like as a river may be only a small stream at its source and by gathering water as it leads on to the sea, become a bulky stream at its mouth; so the sparks on the Leyden-tube gather up electricity from the Leyden-tube, and so brighten away to the tin-foil. But in this flash of lightning, the very reverse appears to take place. The flash is greatly weakened before it reaches the earth, through a transverse discharge to the air. For around the brighter portions of the flash, the air is shining, and streamers are darting earthwards from the flash into the air. At the upper part of the flash, there are also streamers acting manifestly as feeders from the cloud to the flash. The flash rather resembles a long spark from the prime conductor of an electric machine, than the spark of a Leyden-jar; but the prime conductor being metallic, can only imperfectly represent the much lower conduction of a cloud.

In the *Leisure Hour*, September 1889, p. 641, there is an engraving from a photograph of the so-called ribbon-lightning. This form of lightning is clearly produced by a succession o[f] [illegible] motion given to the camera by the hand of the operator, as indeed is there pointed out. The question is, How comes it that the flash so repeatedly passes along the same path? The answer there given is that suggested by Mr. Cowper Ranyard, "That apparently the first flash would heat the air and slightly rarefy it, leaving a path of least resistance, along which subsequent discharges would flow as certainly as water follows the twists and turns of a pipe." It seems to me, however, that a far more important cause for making a second flash to pass along the path of its predecessor is to be found in the action of the transverse discharge, whereby a tubular mass of air becomes electrified around the path of the first flash; and through the electrified air, the flash readily passes, as previously shown. In the woodcut, the effulgence of the surrounding air and the streamers show that the lightning was distributing electricity along its path. The transverse discharge is perhaps never absent from the flash of lightning. In NATURE, vol. xl. p. 543, a flash of lightning which struck a windmill, is described as "a mass or network of flame, which threw off thousands of sparks like fireworks."

The discharging balls of the Wimshurst machine were set one inch apart, everything else remaining as before. The sparks now extended along the glass tube to a distance of about $3\frac{1}{2}$ inches from the tin-foil. The general character of the sparks was the same as before, when the discharging balls were set half an inch apart.

The discharging balls were set $1\frac{3}{4}$ inch apart. When the discharge occurred, the sparks extended along the tube to about $5\frac{1}{2}$ inches from the tin-foil. The sparks were straighter, and not nearly so numerous as when the discharging balls were set at half an inch; they were also very much brighter, but like the others, they all tapered away to nothing. In this experiment, the Leyden-tube was charged to about the highest potential that the machine would give it; and the matter was not any further pursued.

REUBEN PHILLIPS.

1 Bay View Terrace, Northam, Bideford, October 9.

"Darwinism."

WHAT my "laborious essay" "distinctly professes to be" is, as its title-page announces, "an *additional* suggestion on the origin of species"; and this additional suggestion is forthwith stated to be that of "*another factor* in the formation of species, which,

although quite independent of natural selection, is in *no way opposed* to natural selection, and may therefore be regarded as a factor *supplementary* to natural selection." This passage occurs in the most conspicuous part of the paper, viz. at the close of the introduction. In the next most conspicuous part—viz., at the close of the paper itself—it is said, "Without natural selection, physiological selection would be powerless to create any differences of specific type, other than those of mutual sterility, and trivial details of structure, form, and colour."

So much for distinct professions. But as I am tired of controverting the statement that I both intended and perpetrated an "attack" on Mr. Darwin's theory, I will not now burden your columns by supplying the context, or otherwise easily explaining the passages which Prof. Lankester quotes in support of this statement. On a future occasion, however, I hope to avail myself of a more fitting opportunity fully to display the relation in which my "laborious essay" stands to the work of Mr. Darwin; and then I trust it will be clearly seen that, whatever we may severally think about the "complementary principle" of physiological selection, at all events it is in no way hostile to the cardinal principle of natural selection.

Edinburgh, November 19. GEORGE J. ROMANES.

How not to Teach Geometry.

As I have come across an almost unforeseen development of the above heading, I take the liberty of bringing it before your readers. For myself, I may state that I have considered the "learn a proposition off by heart" method was sufficiently bad, but what is to be made of the method described in the following extract from a note which I recently received from my friend:—"We have half of a proposition written on the board, and then we write it at home from memory; then the other half is written on the board, and we write that at home from memory. Then we have to learn the whole proposition at once, to be able to write or say it with different letters. We are not allowed to have a printed Euclid book—we are only allowed to have a book of Enunciations."

Of course this refers to Euc. i. 1.

I beg to commend the above extract to the Association for the Improvement of Geometrical Teaching. I do not know whether to add the name of the school where the above system is followed by one of the teachers.

HERBERT J. WOODALL.

Normal School of Science, South Kensington,
November 11.

P.S.—I should like to see opinions on the teaching described.

A Brilliant Meteor.

Is not the meteor seen from Warwick School on November 4 the same as that mentioned in the following from my daughter, written from the school at Brookfield, Wigton, Cumberland?

"On Monday night (November 4), at 7.55 p.m., when out on the playground viewing the stars, I saw a most beautiful meteor. It seemed to be very near, and was in sight for quite a long time. It appeared just over Skiddaw—that is to say, due south—and went towards the south-east. It had a long tail of light, and burst, and sent out beautiful colours, and disappeared near the horizon."

I may add that, last Sunday, November 10, at about 5.56 p.m., I saw here a very bright meteor pass from a point perhaps south-south-west, and altitude about 25°, to a point perhaps south by east, and altitude about 10° or 12°. It was brighter than Venus when the planet is at its brightest, I think; and it seemed to flash out still more brightly just before disappearing; but the colour did not change perceptibly from its former soft white light, and there was no appearance of bursting. At the time of disappearance, its train of light must have extended over several degrees. WM. SCARNELL LEAN.

Ackworth, November 16.

THE CAUSES AND CHARACTER OF HAZE.

UNLIKE fog, haze commonly occurs in this country when the lower air is in a state of unusual dryness. It is not only a frequent accompaniment of a spell of fine dry weather, but may be, when in combination with certain other conditions, a sign of its approach. Night or morning fogs, and in winter persistent fogs, often signify a calm and settled condition of the air and the prevalence of fair weather. Heavy dews, especially in the autumn, likewise portend fine weather, but usually of shorter duration. Fogs appear usually in one of two conditions: either the air is nearly saturated up to a considerable height, or else is unusually dry, except in a stratum immediately above the ground. In the first case, radiation or condensation from some cause produces, by a slight lowering of temperature, a large precipitation of vapour; and in the second case, radiation from the earth's surface being excessive, owing to the diathermancy of the dry atmosphere, the stratum next the ground rapidly reaches its dew-point, fog is formed, and this fog continues to radiate to the clear sky and further to reduce temperature. Haze, on the other hand, appears often in weather distinguished by unusual dryness, on the surface as well as at a considerable altitude above the ground. The air remains for many days uniformly dry, the nights being nearly dewless, and the sky often free from clouds. The chief difference to be observed, then, is this, that fog requires saturation where it occurs, while haze seems to be favoured rather by a dry atmosphere.

Haze does not prevail on the continent of Europe or in the interior of North America to anything like the same extent as in England; nor, probably, in mid-ocean to the same extent as near the shores of northern countries. On the east coast of Scotland, and, indeed, over all North Britain, it is exceedingly common, especially in the spring, and during the prevalence of east wind, although with west winds the atmosphere is frequently clearer in summer than in Southern England. Over Southern England it is a common accompaniment of winds between east-south-east and north-east inclusive. It appears to prevail more on the eastern than on the western coasts when east winds are blowing. In Western Surrey, when the lower air moves from a westerly direction or is calm, the approach of east wind is announced by a light haze obscuring distant views, before the east wind has actually arrived on the spot of observation. This is not in all cases due to the descent of London smoke from a higher stratum, where the east wind first gains ascendancy, for the phenomenon may be observed in other localities. The haze produced on the first arrival of the east wind is thicker than that which remains when the east wind has gained a strong hold, and the neutral band where calm prevails between a south-west and a north-east current is marked by the thickest mist. In winter a dark fog frequently marks this neutral zone, often not more than one or two miles in breadth, and the zone moves eastwards or westwards according as the west or east wind exercises the strongest pressure. I have frequently observed this phenomenon with great distinctness. In winter, the approach of the equatorial after the prevalence of the polar current is often betokened by a damp fog and the contrary change by a dry fog; the same changes in summer are respectively marked by a great increase of transparency and by a spreading haze or mist. The following observations taken in Scotland illustrate the phenomena accompanying a change from west to east in August. St. Fillan's Hill is a small, steep, isolated volcanic cone about 300 feet in height, standing in the middle of the valley of the Earn, about two miles from the lower end of Loch Earn, in Perthshire. The air was clear, and a fresh westerly breeze was blowing when I was on the summit, about 5 p.m. The breeze suddenly began to slacken, and in about five minutes had dropped altogether. Then down the valley eastwards a blue haze began swiftly to climb the glens tributary to Strathearn, and the whole air eastwards grew obscure. The calm only lasted a little more than two minutes, and then suddenly a strong wind from the east set in, and soon the air, westwards as well as eastwards, was robbed of its transparency. The east wind

continued, and in a few minutes the tops of the hills, which rise precipitately from Strathearn to a height of about 2000 feet, were obscured with cloud-banners growing continuously and descending till in about two hours not only the hills above a level of about 1000 feet, but the whole sky, were covered with gray cloud. The duration of the neutral calm, from two to four minutes, seems to be about the usual time occupied by a moderate east wind in driving back the opposing current, according to my observations in the neighbourhood of London. In the suburbs south-west of London such a change is signalized in the neutral band of calm by a dense yellow haze, producing great darkness, the result of a banking up of smoke to some altitude, together with the condensation of aqueous vapour by the mixture of currents differing in temperature. With lighter winds about equal to each other in momentum, such a band often lasts much longer, and I have known a west wind prevail at Richmond simultaneously with an east wind in London, both without fog, while at Wandsworth, between the two, a calm continued for many minutes, with dense, almost nocturnally-black, smoke-fog, the pressure in each direction being apparently equal. Generally speaking, the mist thus produced at the junction of the two winds is exceedingly dense in winter, moderately dense in spring and autumn, and thinnest in summer, varying, in fact, from a black fog in the cold season to a mere haze in the warmest weather. Hence we have an ascertained condition for the production of haze—the mixture of two opposite winds. It may be here remarked that a very sudden squall of wind from the north, displacing an equatorial or south-westerly current, produces a somewhat similar dense wall of mist, which it soon drives away before it.

Haze very frequently prevails during a north-east or east wind in all parts of Great Britain; in the east of Scotland it is, perhaps, more marked than in other localities, and attends both wet and dry weather. A dense blue mist or haze brought by the east wind sometimes invests the landscape for days before a continuous downpour from that quarter. This haze extends far out to sea eastwards. The southern parts of England are less troubled than the northern by this disagreeable infliction, and the northern parts of France less still. In the eastern counties, and probably in other parts of England, the density of the haze seems to increase in some proportion to the dryness of the air, when only a slight wind blows. On thoroughly rainy days, such as the north-east wind sometimes brings to the London district, the amount of haze is below the average; and when the north-east wind is accompanied by snow-showers, as it often is in February and March, or by rain-showers later in the year, it is remarkably and conspicuously clear. I cannot remember any showery days with a steady north-east wind showing a true haze, beyond the influence of London, but have often observed the extraordinary clearness of such days, and the apparently dissipative action of the air on London smoke.

Generally, the density of the haze is less as the strength of the wind increases. A gale from the north-east is seldom accompanied by much haze inland, although on the east coast the combination is not uncommon. Haze appears to diminish as the north-east wind grows more established, and in winter a long period of this wind may be experienced without the continuance of haze. It is also important to observe that, when high upper clouds are seen to be moving from a direction between east and north inclusive, but especially from north-east, the air is usually clear, and a long continuance of the polar wind may be expected. It is a sign of the firm establishment of the north-east wind when high cirro-cumulus is seen passing over from that direction, whatever deviations may take place temporarily on the earth's surface. The extension of the north-east wind to a great altitude seems to deprive it of its accustomed haziness. When, on the other hand, thick haze accompanies the north-east wind, if upper clouds are in view, they are generally seen to be borne by a different current, and in winter the lower wind does not, in such conditions, often remain long in the same quarter. Hence we have the means of making forecasts with tolerable safety as follows:—

(1) If the lower air be clear, whether clouds at a high level be seen to move from the north-east or none be visible, the lower wind from north-east will probably last some days, perhaps some weeks.

(2) If the lower air be very thick and misty, the north-east wind is not strongly established, and is likely soon to be succeeded either by variable airs and calms, or by breezes from a different quarter.

In spring and summer, haze prevails sometimes for many days together, with a dry atmosphere, over the whole or a large part of Great Britain. The wind is either easterly or variable, the barometer high, temperature high by day and low by night, and the deposition of dew either small or heavy. The haze seems to be uniformly distributed through the atmosphere, and varies neither from one day to another, nor from day to night. The sky is pale blue, the sun rises and sets red and rayless, and the moonlight reveals the blue mist unchanged by the absence of the sun's rays.

Haze has been known to affect a great part of Europe during a period corresponding with the prevalence of drought.

The formation of haze seems to be more common and more sudden in mountainous regions than on the plain. I had once an opportunity of observing the rapid production of a very dense haze from the top of Cader Idris, in Wales. The morning was bright, fine, and clear, but the heat very oppressive. About midday, signs were seen of an approaching thunderstorm, which, however, spent its force at some distance down the valley. Before the storm, a haze quickly gathered, and completely obscured even the nearer ranges. This haze resembled that which prevails sometimes during many hours before the occurrence of a thunderstorm in the level country.

The conditions favourable to the production of haze may be conveniently summed up as follows:—

(1) A gentle wind from east-south-east to north-east inclusive, and east wind in general, especially with dry weather in spring and summer. If the east wind be established up to a great height, the lower air is usually clear, but if the upper current is from a westerly direction, haze prevails.

(2) Fine settled weather, with variable currents, a dry air, and little dew.

(3) Opposition of currents—such as occurs when several shallow barometric depressions exist over the country—and the atmospheric state preceding thunderstorms.

(4) Damp weather, with light winds and varying temperature, as thaw after frost, with snow on the ground.

Turning to those conditions which are most unfavourable to the production of haze, or in which the air is most transparent, we find them to be—

(1) A state of great humidity, such as that which occurs often before bad weather, the wind being between south and west.

(2) Strong winds and showery weather.

(3) Winds between south-west and north.

(4) Fine settled summer weather, with westerly or southerly winds.

(5) Settled easterly or northerly winds, with either clear sky, or high clouds moving from those directions.

(6) Easterly or northerly winds, with a high continuous cloud canopy moving in the same direction, small range of temperature, and steady conditions; or, with detached cumulus in the daytime, and clear nights.

(7) North-west following a wind between north-west and south is particularly clear, except in thundery weather.

It thus appears that the most striking characteristic which may accompany the formation of haze is an unusual dryness of the air, and that a total absence of haze is often observed when the air is unusually charged with vapour. It does not follow that haze, or a light fog much resembling it, is not also seen in a damp state of the air, or that a saturated air is always free from haze; indeed, something much resembling a dry haze does occur with sudden changes of temperature in all ordinary hygrometric states in our climate. But the very condition to which haze in England is commonly, and in a certain sense correctly, attributed—namely, atmospheric humidity—is, if sufficiently uniform and extended, least favourable to its manifestation. A constant moisture-laden westerly breeze would give a climate nearly as clear as that of the south-west corner of France.

Two principal factors go to the production of ordinary haze: the first, a rather large amount of vapour between the earth and a great altitude, say 60,000 feet; and the second, a mixture of two heterogeneous masses of air. Evidence of the correctness of this proposition is to be found in the geographical distribution of haze and the state of the winds when it occurs.

The causes of fog are either radiation of heat from the earth into space and cooling of the overlying humid strata of air to a temperature below the dew-point, or else the mixture of two winds, differing in temperature and other conditions, one of the currents being usually near its point of saturation previous to contact with the other.

If the above-mentioned statement of the causes of haze be correct, we shall be enabled to account for the appearance of haze in certain conditions, which have been given, and for its absence in others. Taking them in order—

(1) A gentle wind from east to north-east inclusive is favourable to haze, especially if it extends to no very great height. Often the approximate depth or height of the easterly current is difficult to ascertain; but, in general, if it be of short duration, it is shallow, and sometimes upper clouds from a westerly direction may be observed. In these cases especially haze prevails. Considering the shallowness of lower winds compared with their extent—an easterly wind, for instance, which has travelled 300 miles beneath a westerly wind only four miles above the earth's surface—it is quite certain that a very large admixture of the two currents must take place. And we may be sure that in the majority of cases the easterly surface wind has above it an upper current from a westerly direction. Mr. William Stevenson (*Edinburgh Philosophical Magazine*, July 1853) observed the cirrus cloud at Dunse, Berwickshire, for eight years, and from his summary of the direction of the motions of that cloud we derive the following figures:—

	Per cent.
Direction of motion of cirri from between south-west and north-west inclusive	75·2
Direction of motion of cirri from between north and east inclusive	10
Other directions	14·8
Direction of wind at surface of the earth from south-west to north-west inclusive	54·6
Direction of wind at surface of the earth from north to east inclusive	32·4
Other directions	13

Thus there remains a difference of over 20 per cent. excess of westerly upper current over westerly surface wind, and at the level of the cirrus a wind between north and east only prevails once to every three occasions of a surface wind from that quarter. The significance of these figures is not seriously affected by the idea, first suggested by Admiral Fitzroy, that visible cirrus is less likely to form in the polar than in the equatorial current, and any careful observer can easily satisfy himself that westerly winds are more common and easterly winds less common at the cirrus level than on the surface. Mr. Buchan ("Handy Book of Meteorology," p. 230) remarks that, as the north-west current advances into southern latitudes, the increasing heat of the sun will tend to dissolve the cirri which mark its course, and he therefore thinks that the north-west upper current is the most prevalent in Great Britain. The actual numbers obtained by Mr. Stevenson during the eight years were 243 for north-west, and 256 for south-west direction of cirrus.

Mr. Ley ("Laws of the Winds," Part I. p. 154) remarks:—"The fact, indeed, that the observed westerly upper currents prevail over the observed easterly upper currents, even more than the westerly surface winds do over the easterly surface winds, has been admitted by most of the observers who have investigated the subject in different parts of Western Europe; and the same phenomenon is noticed in similar latitudes of North America. . . . Be this as it may, the theory of prevalent polar upper currents derives no support from our own collection of examples. Again, the results of the observations classified in Table IV. appear altogether adverse to the supposition that an easterly upper current is common over the northern portions of those depression systems whose westerly winds are the strongest at the earth's surface. . . . Instead of easterly upper currents, we find a great preponderance of southerly currents."

Out of nine balloon ascents recorded in Glaisher's "Travels in the Air," in which the wind at starting from the surface was easterly, there was not one in which a different current was not encountered at a moderate elevation. The changes were as follows:—

Date.	Surface Wind.	Wind at
April 18, 1863.	N.E.	A moderate height, N.
July 11, 1863.	E.	A moderate height, N.
		5400 feet, N.N.W.
May 29, 1866.	N. by E.	Above 2000 feet, N. by W.
		5100 feet, nearly calm.
Mar. 31, 1863.	E., gentle.	Between 10,300 and 15,400 feet, W.
		About 15,400 feet, N.E.
		Higher still, S.W. and W.
Jan. 12, 1864.	S.E.	1300 feet, strong S.W.
		4000 feet, S.
		8000 feet, S.S.W.
April 6, 1864.	S.E.	About 9000 feet, N.W.
June 10, 1867.	Surface calm,	Higher, N.N.E.
	low elevation	Higher still, N.
	N.E.	
Aug. 12, 1868.	N.E.	5000 feet, S.W.
June 16, 1869.	N.E.	10,000 feet, S.W.

On one occasion—January 12, 1864—the temperature from 3000 to 6000 feet was higher than on the surface, but at 11,500 feet it was more than 30° colder—namely, 11°. A large number of balloon ascents show not only a variety of currents, but large and sudden variations of temperature within a few thousand feet.

Thus we may confidently assume, in the majority of cases of east wind, and especially when this wind is of brief duration, local, or gentle, that a westerly wind flows above it at no great distance from the surface of the earth. Considering the perpetual rapid interchanges (hardly to be called diffusion) going on in the atmosphere, the lower wind must be largely mixed with air of a different condition derived from the westerly current. If a cold dry east wind be permeated by patches and filaments, however minute, of moister and warmer air, they must be cooled by contact with the polar wind, and a slight deposition of vapour may take place. Or the countless invisible dust particles may, by increased radiation towards space through a drier air, either cause a slight deposition of moisture upon themselves or collect still smaller particles together, as dust is known to collect on cold surfaces in a warm air. If deposition of moisture take place, the dryness of the air prevents the water particles from growing to anything like the size of the

particles of a fog; a relatively small diffused quantity of vaporous air in minute parcels could not produce by condensation any but extremely small and transitory water particles, in the aggregate visible through long distances, but probably individually beyond the power of the microscope to discern. They may be compared to the blue mist escaping from the safety-valve of a boiler under high pressure: the invisible steam turns for a moment blue, and then to the ordinary white of visible steam. The haze may possibly be equally momentary in duration, dissolving long before reaching the white stage, but fresh filaments are perpetually keeping up the process and giving the appearance of a persistence like that of smoke or dust. According to Espy, every cloud is either forming or dissolving (Buchan's "Handy Book of Meteorology," p. 175).

The action of a north-east wind setting in over England would be represented by a trough of water, say 2 feet square and 2 inches deep, containing warm water flowing in one direction, while cold water enters from the whole length of the opposite side. The cold water would force its way under the warm, and the two opposite currents would continue to flow; but through friction and diffusion there would be a great deal of mixture of portions of the upper with the lower stream.

A haze similar to that accompanying the east wind is frequently seen where two currents of the same wind meet at different temperatures, as at the junction of two valleys, or at projecting headlands (Buchan's "Handy Book of Meteorology," p. 171). It is also common with a humid wind, otherwise clear, when it passes over ranges of hill and valley of moderate elevation, owing probably to the mixture of parcels of air of different temperatures by alternate upward and downward thrusts. The thin white mist which appears in gales from the south-west on sunshiny days is probably due to the forcible and rapid mixture of air warmed by the ground with colder portions from a higher level, the deposition of minute particles of dew being aided by the abnormal amount of salt carried up from the sea in spray, and borne to great distances inland.

A very good instance of the powerful influence of the mixture of two currents of air, not greatly differing in temperature and other conditions, to produce haze occurred on August 26, 1889, in southern Surrey. The wind over a wide area, including the south of England, was variable and gentle from west to north-west. At the place of observation it had been about west-north-west during the afternoon, and the views were fairly clear. Cirro-cumulus, both at a moderate and at a great elevation, moved from north-west. At about 5.30 p.m. the landscape was suddenly invested with haze, which, during the following hour, was thick enough to obscure altogether hills about six miles off. Simultaneously the wind dropped a good deal and shifted to north-west and north for a short time, but soon backed, and the air again became clear about 7.30. It would thus seem sufficient that a reduction of temperature a little more than the ordinary about the time of sunset should occur, in order to precipitate visible moisture upon the dust-particles of the air. Both the sensation and the appearance of the sky resembled that during a disagreeable misty east wind, and, just before the change, a very dark bank of cloud appeared in the north, which, on passing over, was seen to be more mist than a well-defined cloud stratum. It seems not unlikely, judging from the experience of aëronauts, that in this case a current from north or north-east was driven like a wedge into the general north-west wind a few thousand feet or less above the ground.

If the account of the formation of haze in an easterly wind given in the foregoing pages be correct, there should be a clearing of the atmosphere when either the east wind extends itself to the upper regions or the westerly wind succeeds in driving back its opponent out of the lower space. In point of fact, the air does clear itself in either of these events. Moreover, a clearing away of haze is a good indication of a strengthening of the polar current or its expulsion by the equatorial; other signs, such as the motion of cirrus and the aspect of the clouds, plainly informing us which of the two changes will occur.

(2) The second favourable state for the production of haze was given as "fine settled weather, with variable currents, a dry air, and little dew." This state prevails often with anticyclones, and the movement of the air is to a great extent vertical, an interchange taking place between upper and lower strata. Consequently, there is a great mixture of portions of air at different temperatures, with a result like that already described. The heterogeneous character of the lower atmosphere in a horizontal direction declares itself by the poor transmission of sound. But a great deal remains to be explained in the production of haze in these conditions. The cause is probably the same as that which sometimes covers the whole of the British Isles with a damp fog, extending high into the atmosphere. This occurs when two winds of a different character meet in such a manner as to interdiffuse gradually over a wide area. But in the case of haze, how can it endure when the general dryness of the air is far above the point of saturation? Haze sometimes continues in summer right through the day, when the dry and wet bulbs show a difference of 12° to 15°. It would seem as if our methods of estimating the dew-point do not altogether hold for air in a certain condition and for certain particles in it. Is it not possible that condensation to a slight degree may occur upon some minute crystalline particles, such as the salt-dust which pervades our atmosphere, at temperatures above the dew-point? Such action would only be consistent with the effect of crystals in hastening the boiling and congelation of water. It is probable that, if means were available for testing the temperature of successive minute portions or strands of air passing over a thermometer, we should find a great variation from one moment to another. A difference of 12° between the dry and wet bulbs may represent a mean between much higher and much lower values; and on the driest days, when haze prevails, there may be extremely minute portions with a temperature at the dew-point—that is, containing more vapour than, at the particular temperature to which it is a certain moment exposed, can remain uncondensed. That volumes of air at different temperatures take a long time to become thoroughly incorporated, may be regarded as certain. Threads of smoke in a still room often remain for many minutes unbroken, and behave as if they were held together by some cohesive force, and, generally, strains of air or gas at widely differing temperatures, when mixed, tend to hold together rather than to diffuse. Thus, small surfaces, of which the vapour-particles are at different temperatures, are frequently in contact. When we consider that different currents of air frequently prevail within a a few thousand feet of the earth's surface, and that within five miles a temperature of −2° may exist early in September,[1] it seems possible that, in so bad a conductor of heat as air, temperature at different points on the same level may vary greatly. On September 1 and 2, 1889, the condition of the air was instructive with regard to the formation of fog and haze. The night of August 31–September 1 was fine, and radiation rapid, so that in the morning there was a copious dew. From 6 to 8 a.m. there was thick fog, which, as the sun's power increased, lightened and lifted, but the sun did not finally break through till past 11. The wind was fresh from north-east. A thin blue haze remained after the fog had dissipated, and did not altogether disappear during the day. The air was not damp, even before the fog had lifted, though there was a very slight drizzle about 9 a.m. On September 2 the night had been very fine and clear, but in the morning

[1] See "Travels in the Air," Glaisher's ascent of September 5, 1862.

a thick wet fog, with fresh north-east wind, prevailed. This fog cleared, and the sun shone through, about 9 a.m. A mist, however, remained much later. Now, in these cases, the fog was due to the cooling of the earth by radiation (for it did not appear till after midnight) and to the cool north-east wind co-existing with higher currents from a different quarter.[1] The persistence of the haze much beyond the fog reveals the difference between a general saturation and what might be termed molecular saturation. The fog breaks, decreases rapidly, and has gone when the last few shreds of clouds lifted from the earth vanish in the blue, but the haze looks unchanging and uniform over the country. When we see volumes of vaporous air separated, without any apparent reason, into dense clouds and clear intervals, *e.g.* cumulus in a blue sky, it becomes easy to understand that very small microscopic clouds, in which condensation is only momentary, may permeate air otherwise far from saturation.

It would hardly be reasonable to exclude electricity as a possible agent in the otherwise not wholly accountable phenomena of mist and cloud. It may be that the dust-particles of two currents of air differing in electric quality or quantity may be attracted to each other, or that the mixture of currents of different temperature may in some way set up molecular aggregations.

Whatever the cause, we should bear in mind the small quantity of non-transparent matter required to produce the dimming effect of haze. If the eye can observe the colour produced in a drop of water by the fifty-millionth of a gramme of fuchsine, possibly a weight of water or dust not much greater would suffice for visibility in a column of air 1000 feet long. The atmosphere is at all times charged with dust-particles to a degree which it is difficult to realize. The purest air tested by Mr. Aitken previous to his measurements on the top of Ben Nevis, contained about 34,000 dust-particles to the cubic inch—this was on the Ayrshire coast. In every cubic foot there would be 35,232,000 particles, and, in a horizontal column of 1000 feet, 35,232,000,000 particles. It is manifest that a condensation upon a small proportion of these, or an agglomeration of a small proportion into larger groups, or a momentary adhesion by electric attraction, would suffice to produce optical effects.

The evidence concerning the appearance of haze by irregular transmission of light due to unequally heated currents of transparent air seems to be quite insufficient, and however great the heat near the surface of the ground, say in the desert, with consequent distortion of images, it does not, as a rule, bring about the haze so common in temperate climates.

Haze of an abnormal kind need barely be mentioned here—namely, that due to smoke, palpable dust, and the products of volcanoes. It may, however, be very widely spread and very dense. In 1783 Europe was for months covered by the dust ejected by an Icelandic volcano, and the Atlantic for 900 miles west of the north-west coast of Africa is every year subject to a haze composed of fine particles of sand from the Great Desert.

(3) Opposition of currents, such as takes place when several shallow barometric depressions pass over the country, results in mixture of differing air, partial condensation, sultriness, haziness, and frequently thunderstorms. Not at all improbably, the differing electric conditions of two winds, the rapid condensation of vapour, and the projection of highly vaporous air to a great height, accelerate the growth of water-particles, until they fall to the earth in large drops. The saying that thunderstorms advance against the wind is merely a way of asserting that two winds are adjacent, one above the other, and that the clouds move in the upper current. The haze preceding thunderstorms announces beforehand the contention which is going on, and the conglomeration of dust or water particles by electric attraction or rapid cooling.

(4) Damp weather with light winds and varying temperature, as thaw after frost, with snow on the ground. The cause of haze in this condition is obviously the contact of warm moist air with air cooled by contact with, and by radiation towards, the ground. In this case, again, it is mixture of portions of air of different temperatures which produces partial condensation and haze. It must be remembered that the air is always charged with an immense quantity of fine dust, such as particles of salt,[1] that these are capable of radiating, and that when they fall 1° or 2° below the temperature of the air, moisture may be deposited upon them sufficiently to become visible. In the case supposed, of an equatorial current supervening after frost and snow, the mist produced by mixture of parcels of air at different temperatures will be thin and blue if the filaments in which saturation and deposition occur are very small in proportion to the surrounding unsaturated air, and white if the proportion of saturated air is large. For the blue mist or haze indicates deposition in very minute clusters of water-molecules, and instant reversion to the invisible state by the contact of unsaturated air, while the white mist is the result of condensation in much larger quantities in air on the whole very near or at the point of saturation.

Consider next the conditions of weather in which the air is most transparent.

(1) A state of great humidity, such as that which occurs often before bad weather, the wind being between south and west. What does this clearness signify, according to the views of the causation of haze above detailed? Chiefly that the air up to a great height is fairly homogeneous—that is, of the same kind and quality as regards moisture, electricity, and temperature, with due allowance for the normal changes depending on altitude. The humidity is not owing to this homogeneity, but often accompanies it, simply because the south-west and westerly winds have passed over a large extent of ocean. In fact the air throughout has been subjected to the same influences, and nothing has occurred to disturb its uniformity, so that it can for some considerable time carry a large amount of aqueous vapour without precipitation. When precipitation does occur, it is usually by the thrusting upwards of the warmer strata into cold upper strata, and then condensation proceeds without check and rapidly from invisible particles to rain-drops. Thus, on reaching the first mountainous region, or in passing over land heated to a temperature much above that of the sea surface, the ascent of the most humid strata into the cold upper air is often followed by rain. The remarkable transparency before rain signifies a correspondence in direction as well as in qualities between the upper and lower strata. If the wind be between west and south, as it usually is in these cases, we are informed of a similar wind at a high level—that is, that the upper current, as well as the lower, is more than commonly humid, and its vapour tending to condense by passing towards higher latitudes. It only requires slight disturbances in a vertical direction to precipitate the abundant vapour, and hence the frequency of showers, especially where large columns of heated air rise from the land, at a distance from the south coast, and in hilly country. The south-westerly wind being a warm one, is more likely to ascend and to have its vapour condensed to rain than a colder current. The clear lower air indeed owes its clearness partly to its ascending movement.

(2) Strong winds and showery weather. Strong winds usually prevail when the air up to a great height partakes more or less of the same movement. There is

[1] "On Saturday evening, August 31, a balloon, as it ascended, crossed and recrossed Luton several times."—*Daily News*, September 2, 1889.

[1] Salt is shown to be present everywhere in the atmosphere by the spectrum of a flame.

also no opportunity for the filtering through of small portions of dissimilar air, and, if portions do descend into the lower levels, they are broken up, diffused, and dispersed. Still, in the colder half of the year, if the lower wind blows from between east and north, and does *not* extend to a great height, a strong mist may be produced by its being mixed with detached portions of the westerly upper current, which take a long time to be thoroughly incorporated and dissolved, and contain more vapour than they can hold invisible in contact with the cold surface-breeze. Thus the prevalence of much haze with a north-easterly gale indicates an equatorial upper current, and the polar wind is apt to be replaced by it before long. With regard to showery weather, it may almost be said to be the opposite of hazy weather, and for the following reasons:—First, as we have seen above, showers are produced by the upward projection of lower air, containing a good deal of vapour, into upper cold air of the same kind. Then, they are often the expression of a state of the atmosphere when the interchange between the upper and lower strata proceeds by large ascending columns and large down-rushes, instead of by small convection currents, and ascending and descending filaments over a very large area. The clearness of the air with a showery north-east wind is quite surprising, for it is sufficient to banish to a great extent even London smoke. Here, again, the north-east wind prevails to a great height, and the air is homogeneous and rather dry. When a shower or even a cumulus cloud passes over a large town, the smoke is seen to be drawn up in a moving column to the height of the cloud. Probably the chief cause of the clearness of a showery north-east wind is the prevalence, as in other cases, of the same wind in the upper regions, so that there is no admixture of strange threads in its composition, no strands of extra-humid particles to be rendered visible by incipient condensation.

(3) Winds between south-west and north. These are, on the whole, clear for a similar reason, for it has been shown that the upper currents in Great Britain usually move from between south-west and north-west. If, as occasionally happens, an east wind blows overhead, they are very far from transparent.

(4) Fine settled summer weather, with westerly or southerly winds, is clear not only for the reason above stated, but on account of the general moderate dryness of the atmosphere. In such weather, barometric pressure is frequently highest over Spain or France, and our upper currents are accordingly from north-west, becoming warmer as they advance southwards and increasing in capacity for moisture. There would be no condensation if portions of these currents were to descend into the lower air.

(5) Settled easterly or northerly winds, with either clear sky or high clouds moving from those directions. Haze does not form where the wind is steady, the air dry and homogeneous up to a great height, and equilibrium stable, for there is nothing to lead to condensation except at the particular level of saturation where clouds are manifested.

(6) Easterly or northerly winds with a high continuous cloud canopy moving in the same direction, small range of temperature, and steady conditions; or, with detached cumulus in the daytime, and clear nights. The same remarks apply here as to the last.

(7) North-west wind, reaching that point from west or south, is particularly clear. Great transparency in this case is not a sign of rain, but rather of fair weather. It is probably due to its agreement in general direction with upper currents, the increasing dryness as it reaches warmer latitudes, and to the uniformity and equilibrium attained by passing over the ocean.

F. A. R. RUSSELL.

THE PULSION MECHANICAL TELEPHONE.

(FROM A CORRESPONDENT.)

A NEW mechanical telephone of extraordinary power has recently been exciting considerable attention in London and some other cities and towns in this country. It is of American origin, like so many other modern improvements of exceptional character, being the invention of one Lemuel Mellett, I believe of Boston, U.S. There have been many previous mechanical telephones, as your readers are aware, some of which have obtained much publicity for a short time, and then have been heard of but little more; but having had opportunities of experimenting frequently with the new instrument, and observing its vocal power, so to speak, under very various circumstances, I cannot doubt that it has a great future before it.

It may be clearly stated at once that the pulsion instrument is absolutely independent of all electrical aids or appliances, and therefore needs neither battery power to bring it into play, nor insulation of any of its parts to keep them effective. It consists solely of two cheap and simple instruments connected by an ordinary non-insulated wire of copper, or, better still, of a double steel wire, the two parts being slightly intertwisted, say with about a single turn in a couple of feet. The wire (or wires) is simply looped to the instrument at either end, the connection being made in a few seconds. The instrument consists of a disk in combination with a series of small spiral springs inclosed in a case of some three or four inches in diameter. These springs, arranged in a manner that has been determined by experiment, and so as to produce harmonized vibrations, appear to possess the power of magnifying or accumulating upon the wire the vibrations which the voice sets up in the disk, and the wire seems to possess—undoubtedly does possess—the power of transmitting to great distances, and giving out upon a second pulsion instrument, the sounds of the voice.

The ability of this simple system of springs, disks, and wires to convey conversational and other sounds to considerable distances with great clearness and distinctness, reproducing the very tones of the voice and the qualities of musical sounds with but little reduction or modification, is most surprising, and to none more so than to the many men of science who have been recently experimenting with it.

The writer of this notice cannot, perhaps, do better than state his own experiences with this system. After examining and experimenting over several short lengths of wire, some of them exceeding a mile and a half, he last week went to the Finchley Road Station of the Midland Railway, from a point near to which a line had been conveyed to near the Welsh Harp Station, a distance of three miles by the line of railway, and of more by the track of the wire, which for the larger part was carried by the telegraph-posts, to which it was attached by very simple means. Conversation through this length of line, of over three miles, was exceedingly easy; indeed, so powerfully was the voice transmitted, that an ordinary hat sufficed for all the purposes of the second instrument, without going near to which conversation was carried on repeatedly by means of the hats of three gentlemen who were present, the tops of which were merely placed against the telephone wire.

I then went into the garden of the "Welsh Harp," where a short length of wire had been led between two points, the wire on its way from one point to the other being twice tightly twisted, at an interval of some yards, round small branches of trees, of about 1 inch in diameter, being wound round and round the branch three times in each case. Strange to say, this tight twisting of the wires round the branches in no way interfered with the transmission of the voice from end to end of the wire.

A third and last experiment was made with a wire laid obliquely across the Welsh Harp lake, and allowed to sink to, and rest upon, the lake bottom. The length of the line was roughly estimated at about one-third of a mile, and from end to end (excepting a few yards at each end where the wire was led from the water's edge to the telephone box) the wire was completely immersed, and without any other support than the bottom of the lake offered it. Yet, notwithstanding this immersion of the whole wire, conversation was carried on through it by means of the pulsion instruments without the least difficulty. In fact, the voice came through the immersed wire, and the longest wire (of over three miles) previously mentioned, with greater purity and mellowness than through shorter lengths.

I must leave to others to explain, and if necessary to discover, the scientific grounds of the success of this extraordinary little instrument. Looking, however, at its practical capabilities as exemplified above, it is not surprising that Post Office, police, railway, and other commercial people, are already overwhelming with applications those who are arranging to supply the new telephone, which from its extreme simplicity is manifestly a cheap one.

NOTES.

No fewer than 1810 patients bitten by dogs were treated at the Pasteur Institute in the year ending October 31. There were thirteen deaths.

THE *Daily Graphic*, the first number of which will appear on January 4, will be interesting from a scientific as well as from a popular point of view. Twenty years ago, when the *Graphic* was started, so bold an enterprise would have been impossible. At that time the pictures in illustrated journals were produced only by the old method of wood-engraving, which could not, of course, supply all the needs of a daily illustrated paper. By means of various scientific processes, drawings can now be so rapidly and effectively reproduced, that the issue even of a daily illustrated journal may be safely undertaken. The new paper is likely to afford a very striking instance of the influence of these processes on art and journalism.

THE Government of New South Wales has adopted an entirely new scheme of technical education. The present Board of Technical Education is to be abolished, and technical schools will be placed under the direct control of the Education Department. A sum of £56,000 is to be expended in the erection and equipment of a new Technical College and Museum in Sydney, while branch technical schools will be established throughout the country districts. It is estimated that £50,000 will be required annually to carry out the new arrangements.

MR. E. W. COLLIN has been deputed by the Government of Bengal to make inquiries as to the present condition of technical education in Bengal, and to find out what steps should be taken by the Government towards its advancement in that Presidency. The Civil Engineering College at Seebpore, an institution for the training of overseers and civil engineers, is supported by the Bengal Government, but it does not appear that there are any means at present in Bengal for the technical training of artisans. Mr. Collin has addressed a circular to various public bodies asking for information, and he will submit a report on the question about the end of the year.

MR. G. BERTIN is to deliver, at the British Museum, a series of four lectures on the religion of Babylonia. The first lecture will be given on November 26, and the others on the three following Tuesdays, at 2.30 p.m.

MR. G. B. SCOTT, of the Indian Survey Department, who has lately been employed on a survey of the Wards Estates in Bengal, has been placed in charge of the new Cadastral Survey of Upper Burmah.

THE next *conversazione* of the Royal Microscopical Society will be held on Wednesday, the 27th instant, at 8 o'clock.

MR. THOMAS CHILD, who has just returned from Pekin, has sent us very beautiful photographs of the two interesting old astronomical instruments at the Pekin Observatory. These instruments are the most ancient of the kind in the world, having been made by order of the Emperor Kublai Khan in the year 1279. They are exquisite pieces of bronze work, and are in splendid condition, although they have been exposed to the weather for more than 600 years. They were formerly up on the terrace, but were removed down to their present position to make way for the eight instruments that were made by the Jesuit Father Verbiest in 1670, during the reign of the Emperor K'ang Hsi, of the present dynasty.

THE metric system of weights and measures having been adopted in the Photographic Office of the Indian Survey, a series of tables for the conversion of these measures to British, and *vice versâ*, has been prepared by Colonels Thuillier and Waterhouse, Surveyor-General and Assistant-Surveyor-General of India. The scope of the tables, however, has been extended so as to meet, as far as possible, the ordinary requirements of general and scientific reference. The multiples and fractions of the British and metric units have each their equivalent expressed in the other, so that the number requiring to be converted may be multiplied directly by the decimal fraction representing the equivalent value of one unit of the required denomination. The relative equivalents are given for the conversion of measures of length, weight, and capacity, cubic and square measures, and also of British-Indian and metric weights. There are also a few miscellaneous tables that may be found generally useful.

IT is well known that whales can remain a long time under water, but exact data as to the time have been rather lacking. In his northern travels, Dr. Kückenthal, of Jena, recently observed that a harpooned white whale continued under water 45 minutes.

THE elephant skeleton set up in the front hall of the Madras Museum is 10 feet 6 inches high, and it has been stated that this is the skeleton of the largest elephant ever killed in India. Mr. Edgar Thurston, Superintendent of the Museum, in his latest Report, says that this is a mistake. Mr. Sanderson gave 10 feet 7½ inches as the largest elephant he had met, and there is a still larger one in the Indian Museum, Calcutta.

SOME fragments of a gigantic elephant's tusk (we learn from the *Rivista Sci. Ind.*) were lately obtained by Signor Terrenzi, the tusk having been found in the yellow Pliocene (marine) sands of Camartina, Narni. It must have been about 10 feet long. One piece (which seems to have been near the base) measured about 2 feet round at the thickest. The tusk had been broken up by the peasants, and distributed as an infallible remedy for tooth-ache and for belly pains in cattle! It probably belonged either to *E. meridionalis*, Nesti, or to *E. antiquus*, Falc. The finding of elephant remains in the Pliocene marine sands of Italy is not new, but it is rare.

A REMARKABLE paper on "The Ethnologic Affinity of the Ancient Etruscans," by Dr. Daniel G. Brinton, was read before the American Philosophical Society on October 18, and has now been issued separately. Dr. Brinton's attention was specially called to the subject during a sojourn of some months in Italy, early in the present year, when he had an opportunity of studying many museums of Etruscan antiquities. The object of the

paper is to prove that the Etruscans probably came from Northern Africa, and belonged to the same stock as the Kabyles, on the borders of whose country Dr. Brinton had spent some time before his visit to Italy. He thus sums up his conclusions:—(1) The uniform testimony of the ancient writers and of their own traditions asserts that the Etruscans came across the sea from the south, and established their first settlement on Italian soil near Tarquinii; this historic testimony is corroborated by the preponderance of archæologic evidence as yet brought forward. (2) Physically, the Etruscans were a people of lofty stature, of the blonde type, with dolichocephalic heads. In these traits they corresponded precisely with the blonde type of the ancient Libyans, represented by the modern Berbers and the Guanches, the only blonde people to the south. (3) In the position assigned to woman, and in the system of federal government, the Etruscans were totally different from the Greeks, Orientals, and Turanians; but were in entire accord with the Libyans. (4) The phonetics, grammatical plan, vocabulary, numerals, and proper names of the Etruscan tongue present many and close analogies with the Libyan dialects, ancient and modern. (5) Linguistic science, therefore, concurs with tradition, archæology, sociologic traits, and anthropologic evidence, in assigning a genetic relationship of the Etruscans to the Libyan family.

A LAKE-DWELLING has been discovered in the neighbourhood of Somma Lombardo, north-west of Milan, through the draining of the large turf moor of La Lagozza. The Berlin Correspondent of the *Standard*, who gives an account of the discovery, says that this "relic of civilization" was found under the peat-bog and the underlying layer of mud, the former being 1 metre in thickness, and the latter 35 centimetres. The building was rectangular, 80 metres long and 30 metres broad; and between the posts, which are still standing upright, lay beams and half-burnt planks, the latter having been made by splitting the trees, and without using a saw. Some trunks still retain the stumps of their lateral projecting branches, and they have probably served the purpose of ladders. The lower end of these posts, which have been driven into the clay soil, is more or less pointed, and it can be seen from the partly still well-preserved bark that the beams and planks are of white birch, pine, fir, and larch. Among other things were found polished stone hatchets, a few arrow-heads, flint knives, and unworked stones with traces of the action of fire.

MR. R. ETHERIDGE, JUN., contributes to the Report of the Australian Museum, just received, an interesting appendix on the limestone caves at Cave Flat, junction of the Murrumbidgee and Goodradigbee rivers, county of Harden. Having recorded the observations made by him in these remarkable caves, Mr. Etheridge offers some remarks on the Murrumbidgee limestone. This, he says, is of a dense blue-black colour. It is much jointed and fissured, highly brittle in places, with a hackly conchoidal fracture, and crammed with fossils, especially corals. As a display of these beautiful organisms in natural section, he has never seen its equal. Large faces of limestone may be seen, with the weathered corals, and particularly Stromatopora, standing out in relief and in section also. Many of these masses of coral, particularly those of Stromatopora and Favosites, are as much as 4 feet in diameter. The Murrumbidgee limestone has been classed as Devonian by the late Prof. de Koninck, but Mr. Etheridge has not yet sufficiently examined the fossils of this deposit either to gainsay or confirm this view. He thinks it not improbable, however, that Prof. de Koninck's view may be correct.

THE *Comptes rendus* of the Paris Academy of Sciences, of November 4, contains a note by M. A. Angot, on the mean hourly velocity of the wind at the summit of the Eiffel Tower, measured during 101 days, ending with October 1, by means of an anemometer placed at 994 feet above the ground, and compared with the results of a similar instrument at the Paris Meteorological Office, placed at 66 feet above the ground. The average velocity on the tower was 16 miles an hour, being over three times the amount registered at the Meteorological Office, where it was only 5 miles an hour. At the lower station the diurnal variation showed a single minimum about sunrise, and a single maximum about 1 h. p.m. On the tower the minimum occurred about 10h. a.m., and the maximum about 11h. p.m., while the characteristic maximum of lower regions about the middle of the day was hardly perceptible on the tower. It is remarkable that this inversion, which is usual upon high mountains, should occur at so small a height as that of the Eiffel Tower. The ratio of increased velocity was constant at about 5 : 1 between midnight and 5h. a.m.; it then decreased rapidly and became 2 : 1 at about 10h. a.m., and maintained this value until 2h. or 3h. p.m., when it again rose regularly until midnight. These results are of considerable importance to the study of aërial navigation.

THE new number of the *Mineralogical Magazine* opens with an important paper, by Mr. L. Fletcher, F.R.S., on the meteorites which have been found in the desert of Atacama and its neighbourhood. This paper is accompanied by a map of the district. Prof. McKenny Hughes, F.R.S., has a paper on the manner of occurrence of Beekite and its bearing upon the origin of siliceous beds of Palæolithic age. There are also three short papers by Dr. M. F. Heddle, and one by Mr. R. H. Solly.

SOME experiments on the photography of the red end of the spectrum, by Colonel J. Waterhouse, appear in the Proceedings of the Asiatic Society of Bengal for April 1889. In order to render the ordinary commercial gelatine dry plates sensitive to the red rays they are bathed for one or two minutes in a solution of 1 part of alizarin blue ($C_{17}H_9NO_4$) to 10,000 parts of distilled water with 1 per cent. of strong ammonia added. Plates treated with this dye show very intense action through the violet and blue regions as far as *b*; from E to C there appears to be a minimum of action; the sensitiveness, however, increases between C and A, and is strongest between C and B and a to A. Below A the sensitiveness quickly diminishes. Colonel Waterhouse finds that plates saturated with a special preparation of cyanin and sulphate of quinine have their maximum sensitiveness between D and B, but between B and A the action is much weaker than that obtained by using alizarin blue, hence the latter dye is valuable as a ready and simple means of photographing the spectrum between C and A with ordinary dry plates. For orthochromatic photography, rhodomine was found to be almost as efficient as erythrosin, and to be especially useful for photographing the region immediately about D. The photographs were taken by means of Rowland's plane and concave diffraction gratings.

A NEW mode of preparing manganese, by which the metal can be obtained in a few minutes in tolerably large quantities and almost perfectly pure, is described by Dr. Glatzel, of Breslau, in the current number of the *Berichte*. A quantity of manganous chloride is first dehydrated by ignition in a porcelain dish, and the pulverized anhydrous salt afterwards intimately mixed with twice its weight of well-dried potassium chloride. The mixture is then closely packed into a Hessian crucible and fused in a furnace at the lowest possible temperature, not sufficient to volatilize either of the chlorides. A quantity of metallic magnesium is then introduced in small portions at a time, the total quantity necessary being about a sixth of the weight of the manganous chloride employed. Provided the crucible has not been heated too much above the melting-point of the mixture of chlorides, the action is regular, the magnesium dissolving with

merely a slight hissing. If, however, the mixture has been heated till vapours have begun to make their appearance, the reaction is extremely violent. It is therefore best to allow the contents of the crucible, after fusion, to cool down to a low red heat, when the introduction of the magnesium is perfectly safe. When all action has ceased, the contents of the crucible are again heated strongly, and afterwards allowed to cool until the furnace has become quite cold. On breaking the crucible, all the potassium chloride and the excess of manganous chloride is found to have been volatilized, leaving a regulus of metallic manganese, fused together into a solid block, about three parts by weight being obtained for every two parts of magnesium added. The metal, as thus obtained, is readily broken up by hammering into fragments of a whitish-gray colour possessing a bright metallic lustre. The lustre may be preserved for months in stoppered glass vessels, but, when exposed to air, the fresh surface becomes rapidly brown. The metal is so hard that the best files are incapable of making any impression upon it. It is so feebly magnetic that a powerful horse-shoe magnet capable of readily lifting a kilogram of iron has no appreciable effect upon the smallest fragment. It was noticed that the introduction of a small quantity of silica rendered the manganese still more brittle, and caused it to present a conchoidal fracture, that of pure manganese being uneven. The specific gravity of the metal, former determinations of which have been very varied, was found to be 7·3921 at 22° C. This number, which was obtained with a very pure preparation, is about the mean of the previous determinations. Dilute mineral acids readily dissolve the pulverized metal, leaving a mere trace of insoluble impurity. It is also satisfactory that practically no magnesium is retained alloyed with the manganese, and the introduction of carbon is altogether avoided by the use of this convenient method.

THE additions to the Zoological Society's Gardens during the past week include a Common Marmoset (*Hapale jacchus*) from South-East Brazil, presented by Mr. O. Burrell; a Common Squirrel (*Sciurus vulgaris*), British, presented by Miss B. Tatham; a Common Stoat (*Mustela erminea*) from Northamptonshire, presented by Mr. Cuthbert Johnson; a Wattled Crane (*Grus carunculata*) from West Africa, presented by Mr. Robert Sinclair, Jun.; a Redshank (*Totanus calidris*) from Devonshire, presented by Mr. R. M. J. Teil; a White-backed Piping Crow (*Gymnorhina leuconota*) from Australia, presented by Mr. W. H. Felstead; a Grey-headed Porphyrio (*Porphyrio poliocephalus*) from India, presented by Dr. Gerard Smith; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. G. W. Alder; a Dwarf Chameleon (*Chamæleon pumilus*) from South Africa, presented by Mrs. Leith; a Green Lizard (*Lacerta viridis*), European, presented by Mr. C. H. Whitlow; a Common Jay (*Garrulus glandarius*), European, purchased; five Carpet Snakes (*Morelia variegata*) from Australia, received in exchange.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m., November 21 = 2h. 3m. 21s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G. C. 527	—	—	2 15 28	+41 35
(2) 15 Arietis	6	Yellowish-red.	2 4 31	+18 59
(3) α Arietis...	2	Yellow.	2 1 0	+22 57
(4) β Trianguli	3	Bluish-white.	2 3 0	+34 28
(5) DM + 56° 724 ...	9	Reddish-yellow.	2 42 32	+56 31
(6) R Tauri	Var.	Very red.	4 22 16	+ 9 55

Remarks.

(1) Sir John Herschel's description of this nebula is as follows:—! Bright, very large, very much extended. The spectrum has not yet been recorded.

(2) This is a star of Group II., in which Dunér records bands 2–8, but states that they are neither wide nor dark. The star falls in species 13 of the subdivision of this group, and is well advanced towards Group III. Metallic lines, and possibly hydrogen lines (dark) may therefore be expected. In the earlier stages of the group, no hydrogen lines appear, the radiation from the interspaces between the meteorites being balanced by the absorption of the gas surrounding the incandescent stones; but in the more advanced members, as in α Orionis, the absorption will probably be found to slightly predominate. The presence or absence of the F line, and of metallic lines, and their relative intensities, should therefore be noted.

(3) This is a star of either Group III. or Group V., and the usual criteria (see p. 20) should be observed in order to determine which. At the same time, the relative intensities of the hydrogen lines and the metallic lines (say *b* and D) should be recorded, so that the star may be placed in a line of temperature with others.

(4) According to Gothard this is a star of Group IV. The usual observations are required.

(5) Dunér classes this with Group VI. stars, but states that the type of spectrum is a little doubtful. Further observations are therefore required. As the most advanced stars of the group are very red, the colour of this star indicates that it probably belongs to an early stage of the group, in which the carbon bands would be narrow, and therefore somewhat difficult to observe with certainty; in that case traces of *b* and D might be expected. The colour should also be checked.

(6) Gore gives the period of this variable as 325·6 days, and the range as 7·4–9·0 at maximum to < 13 at minimum. The maximum will occur on November 30. The spectrum is of the Group II. type, and belongs to species 9. Dunér states that the dark bands, especially 7 and 8, are very wide. In several variables of this class (R Leonis, R Andromedæ, &c.), Espin has observed bright hydrogen lines near maximum, and the question is, Is this common to all the variable stars of this type? As stated with reference to 15 Arietis, under normal conditions the hydrogen lines in the earlier species of the group are absent, because the interspacial radiation balances the absorption; but if through some cause the temperature increases at maximum, more hydrogen would be driven into the interspaces and radiation would predominate. It may be mentioned that, according to the meteoritic theory, the increase of temperature and luminosity is brought about by the periastrion passage of a secondary swarm through the outliers of the central one. It is not unlikely that slight variations of colour will take place from maximum to minimum, and it is important therefore that the colour should be noted when the spectroscopic observations are made.

A. FOWLER.

THE MINIMUM SUN-SPOT PERIOD.—M. Bruguière, in *L'Astronomie*, November 1889, gives a series of observations made with a view to determine the exact date of the minimum sun-spot period. The following tables show the condition of the sun's surface with respect to spots from the beginning of January to the end of July of this year:—

Date, 1889.	No. of days without spots.	
Jan. 3–15	13	
,, 18–31	14	
Feb. 8–21	14	
Mar. 2–6	5	
,, 17–31	15	
April 11–30	20	25
May 1–5	5	
,, 10–26	17	
,, 28–31	3	18
June 1–15	15	
,, 29–30	2	13
July 1–11	11	
,, 25–27	3	

Date, 1889.	No. of days with spots.
Jan. 16–17	2
Feb. 1–7	7
,, 22–29	8
Mar. 1 and 8–16 ...	10
April 1–10	10
May 6–9	4
,, 27	1
June 16–28	13*
July 12–24	13*
,, 28–31	4

* The same spot.

If the small spots that were seen from May 6–9, and also on May 27, be neglected, it will be seen that there would be a period without spots extending from April 11 to June 15—that

is, sixty-six days; but if these small spots be considered we find an interval of twenty-five days without spots—namely, from April 11 to May 5. The minimum period, therefore, appears to have passed about the end of April, this being the time when the greatest number of days passed without spots being observed on the sun. The new period opened with the appearance of a large spot on June 16.

RETURN OF BRORSEN'S COMET.—The following elements and ephemeris for this comet are given by Dr. E. Lamp in *Astronomische Nachrichten*, No. 2933:—

T = 1890 February 24·1358 Berlin midnight.

$$\left.\begin{array}{l} \omega = 14^\circ\ 55'\ 35''\cdot89 \\ \Omega = 101\ \ 27\ \ 33\cdot74 \\ \iota = 29\ \ 23\ \ 48\cdot25 \end{array}\right\}\text{Mean Eq. 1890·0}$$

$$\phi = 54\ \ \ 7\ \ 46\cdot19$$

$$\mu = 650''\cdot3693$$

Ephemeris for Berlin Midnight.

THE COMPANION OF η PEGASI.—A companion to η Pegasi was discovered by Sir William Herschel in 1780, and subsequently observed by South in 1824. Its magnitude has been rated from twelve to fifteen. Mr. S. W. Burnham, however, notes (*Astronomische Nachrichten*, No. 2933) that, using the 36-inch refractor at the Lick Observatory, the Herschel companion appears as a close double. South's mean of two measures is given in his catalogue as:—

1824·84 338°·9 89″·82 2*n* S.

The following is the mean of four measures made at Mount Hamilton:—

η Pegasi.

B and C.					A and BC.		
1889·53	83°·3	0″·29	10·1	10·1	1889·53	339°·0	90″·38

The close pair is difficult, and can hardly fail to be a physical system, and Mr. Burnham thinks that, although it is not a test for the large telescope, it will not be seen with any small instrument.

GENERAL BIBLIOGRAPHY OF ASTRONOMY.—The second part of Vol. I. of this comprehensive bibliography has been published. It represents Houzeau's last work, and hence it is well that his biographical note, by A. Lancaster, should be included. The first part of Vol. I., published in 1887, contained the references to historical works and those relating to astrology; the part just published contains the references to biographies of astronomers and their epistolary communications, general astronomical works, astronomical societies and their proceedings, and everything relating to spherical astronomy. Works on theoretical astronomy are also well represented. The third and last part of Vol. I. is now in press, and contains references to all the published matter on the mechanism of the heavens, physical, practical, and descriptive astronomy, and the systems of cosmogony. The utility of this bibliography, when completed, needs no comment.

J. C. HOUZEAU'S "VADE MECUM."—With reference to our biographical note on J. C. Houzeau (p. 20), M. A. Lancaster writes to remind us that Houzeau's "Vade Mecum" was issued after the appearance of the second volume of the "Bibliographie Générale de l'Astronomie," the publication of which began in 1879. Moreover, the "Vade Mecum" was only a second edition of the "Répertoire des Constantes de l'Astronomie," inserted in 1877 in the first volume of the new series of the "Annales Astronomiques" of the Brussels Royal Observatory. The numerous materials brought together for the "Bibliographie Générale" suggested to Houzeau the idea of issuing a new edition of the "Répertoire" considerably corrected and enlarged.

A NEW COMET.—A new comet was discovered on November 17 by Mr. Lewis Swift, of the Warner Observatory, Rochester, New York. Place at November 17, 6h. 35m. 2s. G.M.T.; R.A. = 22h. 42m. 24s.; N.P.D. = 78° 9′. Daily motion in R.A., + 2m.; in N.P.D., − 15′. The comet was only faint.

MIRAGE IN THE SOUTH AMERICAN PAMPAS.

I WAS staying in the Pampas of the Argentine Republic, near Melincue, a small town of the Province of Santa Fe, from September 1888 to March 1889. During my stay I had the opportunity of observing certain mirage phenomena. It is possible that my notes may contain something of interest. They were, designedly, taken without reference to any previous knowledge of the theory of mirage that I might possess.

To illustrate my observations I had drawn *eight* diagrams; but, for the purpose of insertion in NATURE, I have been obliged to reduce these to *two*. Hence I fear that my descriptions may not be as clear as I should wish.

The most general conclusion at which I arrived was that there were *two* classes of mirage of very different character. The one I shall call "the summer mirage," the other "the winter mirage." I would observe that, without a telescope of some sort, one would be unable to make observations of much value; and that, as I had but a binocular telescope, in many details I failed to make out as much as I could had I possessed a larger telescope steadily mounted.

I. *The Summer Mirage.*

(1) This mirage is seen in full day. I was told that in normal years it is most remarkable in the extreme heat of summer. The summer of December, January, and February 1888 and 1889 was abnormally wet, however. And I myself saw the mirage most frequently in spring (September, October, and the earlier part of November), the grass being then short and very dry. Later on the grass became very long, and unusually green and damp, owing to the heavy rains. And then I saw the mirage but rarely in the grass plains, though on the several occasions on which I passed, in the blaze of a summer day, the dry sandy bed of an old laguna, the mirage was there to be seen very clearly.

On one or two occasions in spring I saw the mirage when there was a fairly cold wind and no perceptible sunshine, but still in full day.

(2) This kind of mirage usually appeared as a strip of "water" running more or less parallel to the horizon, at one end narrowing to a point, and at the other end opening out into the sky. It appeared much as an arm of the sea, or an estuary, seen near the horizon, and running parallel to it. The "water" was of the same colour as the sky above it near the horizon.

(3) Viewed through glasses, the whole of the land seen above and beyond the "water," the "water" itself, and to a less extent the land seen just this side of it, appeared wavy and ill-defined, flocculent, and (when there was any breeze) possessed of a drifting movement down the wind. At the thin end of the "water," and just beyond it in the line of the layer, one could see broken fragments of "water" drifting over the land; and, in like manner, the peninsula of land appeared to end in a line of drifting fragments.

(4) It appeared to me that the land seen beyond the watery layer was either within the limits of the natural horizon, or not much beyond them. One did not, as one did in the "winter mirage," see houses, &c., that were normally out of sight.

(5) Cattle, &c., seen in the watery layer were ill-defined. But on the whole it seemed that their legs were hidden, and bodies were reflected inverted, much as if they had been standing in shallow water.

(6) When I mounted higher, a mirage, if seen at all, was further off than when I stood lower.

If, when looking at the watery layer of a mirage, I mounted higher, the "water" narrowed, and the strip of land beyond it widened, until at a certain height of my head the "water" had narrowed into a wavy line of fragments. Further mounting caused the "water" to disappear. If, on the contrary, I stooped, the "water" appeared to widen, the strip of land above it to narrow, until at last the mirage joined the sky.

On one occasion, when the mirage was about a mile and a half distant, and on another occasion when about 250 yards distant, I caused the "water" to appear and disappear by a vertical movement of my head not exceeding 1 foot.

(7) Objects situated in the watery layer but rising out of it, or on the strip of land beyond it, were reflected in the "water" much as in true water; but all was ill-defined, and the inverted reflections often broken and lengthened.

(8) It appeared to me that objects on the strip of land beyond the watery layer were also to be seen faintly reflected in the land that lay between them and the 'water." And when, as in (6), I had raised my head until the "water" had just dwindled away, objects near the horizon were reflected inverted in the region from which "water" had vanished.

(9) By the aid of my glasses I came to the conclusion that objects were not really, as they appeared to the naked eye, "drawn up" by the mirage. But it seemed rather that, an object being seen above its (often elongated) reflected image, and both being ill-defined, to the naked eye the whole appeared like the object "drawn up." In this way clumps of grass appeared as trees.

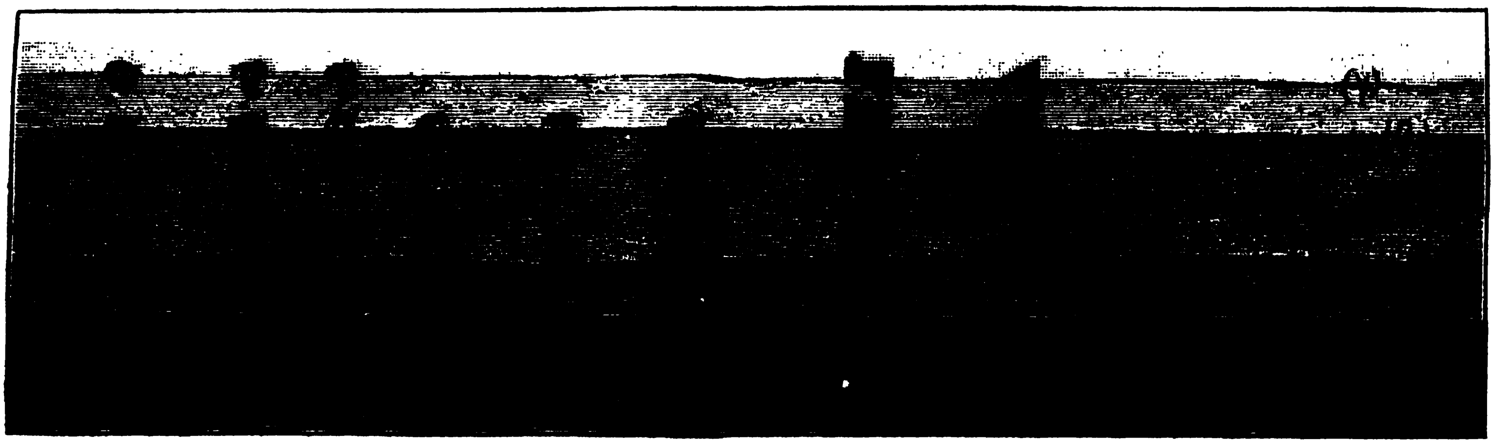

FIG. 1.

(10) In (1) I have mentioned the usual form of the mirage. But with various slopes, &c., of the ground, the form of the mirage varied. Sometimes the "water" opened out into the sky both ways; and several times I saw an isolated patch of "water" over an isolated patch of bare hot earth.

Conclusions as to Summer Mirage.—It seemed, then—

(1) That this mirage was due to a layer of relatively warm air close to the earth.

(2) That this mirage-giving layer was not more than about feet in depth, and that it may have been less.

(3) That there were not, to any noticeable extent, vertical elongations of objects nor extensions of normal horizon.

(4) That in this mirage there were no images, erect or inverted, seen above the real object.

In fact, it seemed that the sky and terrestrial objects were simply reflected in a sheet of warmer air lying close to the ground. (Of course the paths of the rays would be curved.)

II. *The Winter Mirage.*

[I was told that this mirage is seen in winter, and best on fine mornings after hard frost. What I saw were, it seemed, but poor specimens.]

(1) I saw this mirage several times, always about sunrise and after a frost. Before sunrise, as soon as there was any light, I looked out into the plains with my binoculars. It appeared as if the horizon were higher than usual, and that one could see tracts of land, with houses and other objects, that were usually concealed below the horizon.

FIG. 2.

Further, it seemed that this extension of horizon was not really continuous, as it at first appeared, but that it was divided into layers. As far as I could judge, the line (α) was beyond the normal limits of the horizon, the tract from (α) to the limit (β) was more or less a repetition of the tract below (α), and from (β) to (γ) was again more or less a repetition of the same tract. As to what one could see above the line (γ), I could make no trustworthy observations.

Before sunrise, this extension of the horizon was seen all round; and, though the layers referred to could be distinguished fairly well, there were as yet no "watery layers" to be seen.

The land seen just above the lines (α) and (β) was paler than that seen just below these lines.

(2) Thanks to a most convenient distribution of cattle of various colours, and of other objects, I was able, with the aid of my glasses, to make out a good deal.

But the images changed as the cows moved, the appearances varied as time went on, and were so different in different parts of the horizon, that I could only arrive at some general conclusions.

There would be, for example, just below, or on the edge of, the line (α), a cow. This I will call the "*first cow*," or the

"original cow." Just below or on the line (β), vertically above the *first cow*, and, like it, erect, would be a *second cow*, a repetition of the first. And often, above this again, below or on the line (γ), would be a third cow, also erect.

Sometimes there were confused images hanging from the *second cow* and joining other confused images piled on the *first cow*; sometimes the first cow was clear of images, while they hung down from the second cow; sometimes the second cow was clear, and there were images piled on the first. Often the *third cow* was missing (see Fig. 1). As the original cow moved, these images changed their disposition or vanished, and the third cow appeared or vanished. But in all these changes it seemed to me that the *first cow*, *second cow*, and (when visible) the *third cow*, were the permanent images. These, it appeared, were always erect.

(3) After the sun had risen, all continued *in statu quo* for a short time. But soon, at various parts of the horizon, the land just above the edges (α), (β), and (γ) paled away, and finally melted into the appearance of "sky" or "water." There were left, in the later stages of the mirage, first, the plain itself, with an extension, the limits of which were not sharp, beyond the normal horizon; secondly, above this a strip of land, apparently suspended in the air; thirdly, in some parts of the horizon another strip of land suspended in the air above this again. The interval between (α) and (β) was in all stages greater than that between (β) and (γ). One of the appearances in the later stages is indicated in Fig. 2.

Other changes crept in, too. Very often the original objects were wholly or partly sunk out of sight; the images were less defined; and the confused images hanging from the *second cow*, *e.g.*, or piled on the *first cow*, were now seen in the watery layers, sometimes bridging it over.

(4) As time went on, the watery layers widened. The images, too, became still vaguer, and the original objects were usually out of sight or only just indicated above the line (α). Moreover, the aërial images, with their confused trails of images hanging from them, began to assume more the appearance of "inverted images suspended over objects hidden below the horizon."

(5) In these later stages, no doubt, anyone would have guessed that the aërial images were indeed very vaguely defined *inverted* images. But to me, as I followed the phenomenon from the beginning, it seemed that they were not so. It seemed to me that each aërial image was really topped by an *erect* image, which, with the trails hanging from it, seemed like an inverted image. At least I can say that, so long as the images were well defined at all, I never made out a clear case of the *main*, or permanent, aërial images being inverted. Thus, as the *first cow* moved, it was the erect *second* (and sometimes *third*) *cows* that remained clear.

(6) In these later stages it was only trees and houses that could be seen in the mirage, and these were ill-defined.

(7) The mirage lasted until about an hour and a quarter after sunrise. The last traces of aërial images of land appeared just under the sun, and in that part of the horizon that lay just opposite to it. Whether the abnormal extension of the horizon entirely ceased at the same time, I cannot say; but there did not remain any noticeable extension.

(8) As with the summer mirage, I found I could alter appearances by altering my level above the earth. But the change in level had to be more considerable. I have no good notes on this matter; but I believe that usually I could recover a past stage of the mirage by a sufficient descent down a ladder from my post of observation.

General Conclusions as to Winter Mirage:—

(1) It is due to the earth, and the air near it, being considerably chilled below the temperature of the rest of the atmosphere.

(2) The phenomena of extended horizon and multiple images are to be observed.

(3) The "drawn up" appearance of objects is really due to a number of images piled upon one another, only to be separated by the use of a telescope.

(4) No case of a terrestrial object having above it a single inverted image, or images of which the uppermost was inverted, came under my notice.

W. LARDEN.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xii. No. 1, and index to vols. i.–x. (Baltimore, 1889).—This volume opens with an instalment of sixty pages of a memoir by A. R. Forsyth, F.R.S., on "Systems of Ternariants that are Algebraically Complete." In this the writer has found it convenient to use "'ternariant' as a generic term for concomitants of ternary quantics, instead of giving it the signification which Prof. Sylvester proposed (*Amer. J. of Math.*, vol. v. p. 81) to give to it, viz. the leading coefficients of those concomitants." The memoir is divided into three parts, and deals with the theory of the algebraically independent concomitants of ternary quantics, taking as the starting-point the six linear partial differential equations of the first order satisfied by them. References are supplied to numerous memoirs on the subject.—Captain (now Major) P. A. Macmahon continues (pp. 61–102) his investigations (vol. xi. No. 1) in a "Second Memoir on a New Theory of Symmetric Functions." Herein he is engaged with functions which are not necessarily integral, but require partitions, with positive, zero, and negative parts for their symbolical expression. The author thus summarizes his results: (1) a simple proof of a generalized Vandermonde-Waring power law which presents itself in the guise of an invariantive property of a transcendental transformation; (2) the law of "groups of separations"; (3) the fundamental law of algebraic reciprocity; (4) the fundamental law of algebraic expressibility which asserts that certain indicated symmetric functions can be exhibited as linear functions of the separations of any given partition; (5) the existence is established of a pair of symmetrical tables in association with every partition into positive, zero, and negative parts, of every number, positive, zero, or negative.—The closing portion of the number (pp. 103–114) is taken up with an article entitled "De l'Homographie en Mécanique," by P. Appell.—A likeness of M. Poincaré faces p. 1.—The index is of a twofold description—of authors and of subjects. From the forewords we learn that papers have been published from eighty-nine contributors; these comprise "most of the leading mathematicians of the world."

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, November 11.—M. Hermite in the chair.—Presentation of Report of Proceedings of the permanent International Committee for preparing a photographic chart of the heavens, by M. E. Mouchez. Fifteen Observatories will be ready by the middle of next year; and five others before the end. The zones are indicated.—Note of M. Daubrée with descriptive catalogue of the meteorites of Mexico prepared by M. Antonio del Castillo. Meteorites are abundant in Mexico. A remarkably wide area of dispersion is indicated by three portions of one mass, found at the angles of a triangle, whose two longer sides were 90 km. and 60 km. In one of these places two plates were found 250 m. apart; and they seem to have formed one huge plate over 24,000 kgm. weight, which broke near the ground.—On the incineration of vegetable matters, by M. G. Lechartier. Trying various methods, he finds, that in the carbonization and incineration of a plant, there is considerable loss of sulphur, volatilized in various combinations; and special precautions are necessary in determining this constituent. Under the same conditions, and care being taken to prevent loss of solid matter carried away mechanically with the issuing gas, there is no sensible loss of phosphorus.—M. Picard was elected member in Geometry, in place of the late M. Halphen.—On a rotating magnetic field formed with two Ruhmkorff coils, by M. W. De Fonvielle. A current from accumulators is sent through the primary of one coil, the secondary of which is connected with that of the other coil, which is in a line with the first, and the primary of which may be open or closed.—On certain ellipsoidal areas, by M. G. Humbert.—On a new calculating machine, by M. L. Bollée. While in previous machines, multiplications, *e.g.*, are done by successive additions, this one has a multiplying apparatus which determines immediately, in one function, the product of a number by each figure of the multiplier.—On the solubility of the chlorides of potassium and of sodium in the same solution, by M. Étard. The results of experiment are shown in graphic form; the curves of solubility of each salt separately being compared with those of the mixed salts, &c. The sum of the dissolved salts is represented by a continuous straight line. The curves for the mixed salts cross at temperature 97°; that for NaCl falling while the other rises.—On an application of thermo-chemistry, by M. A.

Colson. The formation of nicotine monohydrochloride liberates about twice as much heat as that of the dihydrochloride under like conditions; hence a probable difference in constitution of the two nitrogen groups of nicotine. The action of nicotine on coloured reagents shows at once a difference in the two basicities.—On the myelocytes of fishes, by M. J. Chatin. In fishes, as in other zoological groups, the nervous elements termed myelocytes, are not to be referred to a special histic type, but to the nerve cell; which is simply modified, chiefly by enlargement of the nucleus, and corresponding reduction of the somatic part.—On the continuity of the pigmented epithelium of the retina with the external segments of the cones and rods, and the morphological value of this arrangement in vertebrates, by MM. R. Dubois and J. Renaut. This new fact makes it probable (according to the authors) that in the retina of vertebrates a similar process occurs to that in the light-sensitive apparatus of Mollusks like *Pholas*; by mechanism of impression and transformation of luminous movement into contractile, then sensorial.—On strabismus, by M. H. Parinaud. The immediate cause of the deviation (in squinting) is a disorder of innervation, excess in convergence, defect in divergence, caused generally by the accommodative effort in one case (hypermetropia), and the little use made of accommodation in the other (myopia). The deviation, when sufficiently fixed and prolonged, induces anatomical changes both in the brain-connections and the tissues of the eye (in the latter case, not only shortening of muscles, but retraction of all relaxed fibrous parts, especially Tenon's capsule). This has important bearings on treatment.—On the morphology and the biology of the fungus *Oidium albicans* (Robin), by MM. G. Linossier and G. Roux. Besides the *yeast* form, and the *globulofilamentous*, he finds a third, similar to *chlamydospores*, and probably needing some new natural habitat for full development. This fact, with the absence of *ascospores*, &c., suggests removal of the organism from the genus *Saccharomyces*. Again, it is found, that in culture of the fungus, the complication of form increases with the molecular weight of the aliment; there is a growing tendency to form long thin filaments. This tendency is also favoured by high temperature, excess of oxygen, a trace of nitrates, and antiseptics.—Comparative activity of various digitalines, by M. Bardet. He compares crystallized and amorphous digitaline, prepared according to the French codex, German *digitoxine*, French *digitaleine*, and German *digitaline* (the power of the two last is much less than those of the others).

MR. STANLEY.

MR. STANLEY'S latest letters, which have been exciting universal attention, present as fascinating a record of travel, adventure, and geographical discovery as any that has ever awakened the interest of civilized mankind. It is impossible to read them without the warmest admiration for the writer's resolute energy, inexhaustible resource, and dauntless courage. No previous traveller can have been confronted by a greater number of formidable—often apparently insurmountable—difficulties. Mr. Stanley never allowed himself to be disheartened by the obstacles in his way, but pressed steadily on, varying his methods to meet changing needs, until the immediate object of his great enterprise was attained. Not the least serious of his perplexities sprang from the reluctance of Emin Pasha to be "rescued." It was not unnatural that Emin should hesitate to quit a region for which he had made so many sacrifices, and with regard to which he had entertained so many hopes; but it is certain that if he had remained he would soon have fallen a victim to treachery. Happily, Mr. Stanley, after many an argument, succeeded at last in overcoming his scruples and hesitations, and on April 10 the two men, accompanied by a party of about 1500 persons, including native carriers, started from the southern shore of Albert Nyanza on their homeward journey. No part of Mr. Stanley's narrative is more interesting than that in which he tells the story of his efforts to persuade Emin that he might with honour resign a task which had already been practically taken out of his hands. The tale brings out vividly a most striking contrast between two types of character, each of which in its own way commands our sympathy and respect.

The scientific results of Mr. Stanley's journey are full of interest, and form a most important addition to our knowledge of Central Africa. On April 11 (NATURE, vol. xxxix. p. 560) we gave an account of his geographical discoveries so far as they were then known; and anyone who will consult the map which we printed on that occasion will be able to trace without difficulty the main lines of the explorer's later course. In 1877 Mr. Stanley discovered Muta Nzige, which he now calls Lake Albert Edward. This lake is less extensive than was originally supposed. At the time of its discovery it could not be determined whether its waters were discharged into the Nile or the Congo, but now Mr. Stanley has found that it is one of the feeders of the former river. It receives all the streams of the south-western part of the Nile basin, just as Victoria Nyanza receives all the streams of the south-eastern part of the Nile basin. The two lakes discharge their waters into Albert Nyanza, whence flows the White Nile. Lake Albert Edward and Albert Nyanza are connected by a river called the Semliki, whose valley Mr. Stanley vividly describes.

Lake Albert Edward occupies the south-western end of a great area of depression, at the north-eastern end of which lies Albert Nyanza. This area of depression lies between 3° N. lat. and 1° S. lat., and is from 20 to 50 miles broad. East and west of it rise extensive uplands, those on the western side forming the water-parting between the Nile and the Congo. Towards the east, beyond the valley of the Semliki—that is, the central part of the line of subsidence—is a great mountain range called Ruwenzori, "the Mountains of the Moon," culminating in peaks which Mr. Stanley estimates to be between 18,000 and 19,000 feet. Past this splendid range the party advanced on their way southwards. Says Mr. Stanley:—"Much as we had flattered ourselves that we should see marvellous scenery, the Snow Mountain was very coy, and hard to see. On most days it loomed impending over us like a tropical storm-cloud ready to dissolve in rain and ruin on us. Near sunset a peak or two here, a crest there, a ridge beyond, white with snow, shot into view, jagged clouds whirling and eddying round them, and then the darkness of night. Often at sunrise, too, Ruwenzori would appear fresh, clean, brightly pure; profound blue voids above and around it; every line and dent, knoll, and turret-like crag deeply marked and clearly visible; but presently all would be buried under mass upon mass of mist until the immense mountain was no more visible than if we were thousands of miles away. And then, also, the Snow Mountain, being set deeply in the range, the nearer we approached the base of the range, the less we saw of it, for nigher ridges obtruded themselves and barred the view. Still we have obtained three remarkable views—one from the Nyanza Plain, another from Kavallis, and a third from the South Point."

Lieutenant Stairs tried hard to reach the loftiest summit, but succeeded only in attaining a height of 10,600 feet, which was separated from the snow-covered peaks by deep ravines. He is of opinion that the central mass of the Ruwenzori range is an extinct volcano, and that certain jutting pinnacles on the sides of the mountains are survivals of the time when volcanic forces were in full activity. So much of the *débris* is borne along by the Semliki that the southern part of Albert Nyanza is being rapidly filled up.

Mr. Stanley has much that is new to tell us, not only about Albert Nyanza and Lake Albert Edward, but about Victoria Nyanza, a great south-western extension of which he has discovered. About the many tribes through whose territories he passed he has also a vast amount of curious and suggestive information, offered with all the freshness due to his immediate contact with the facts he describes. Nothing could be better in its way than his account of the Wakonju, a tribe from whom he and his people received much kindness. They occupy the slopes of the Ruwenzori Mountains, on which some of their villages are built at a height of 8000 feet. Here they have taken refuge from their enemies the Warasura. It is noteworthy that in many parts of the Central African uplands which he visited Mr. Stanley found a physical type which he identified with that of the Abyssinians. On these and many other points of interest the world may expect soon to receive from him further enlightenment. Meanwhile, we desire to join most cordially in the expressions of high appreciation that have been everywhere evoked by his success, and by the great qualities of intellect and character by which it has been achieved. Such geogra-

phical labours as his are unsurpassed in hardship, and the results obtained make his work one of the most important and fruitful researches of the time.

THE HABITS OF THE SALMON.

The Habits of the Salmon. By John P. Traherne. (London: Chapman and Hall, 1889.)

THE Stormontfield breeding-ponds have taught us much of the history of the salmon from the eggs to the smolt stage. After that he passes to the sea, beyond the reach of observation, and, with the exception of what we have learned from the return to the rivers of fish that have been marked before their passage to the sea, all that purports to be knowledge of the habits of the fish is really only guesses at truth.

Theories by a practical salmon-fisher, of wide experience, are entitled to respectful examination. This Major Traherne can claim; more than that he does not claim. The arrangement of the chapters in the book is objectionable as tending to confusion. It would be preferable to take first the chapter on smolts, and then to follow the life of the fish through its grilse, salmon, and kelt stages.

Notwithstanding that "smolts bred in the Stormontfield, Howietown, and other fish ponds have never as yet been known to evince the least desire to go to sea before the spring months," yet Major Traherne is of opinion, and supports his opinion with good evidence, that there is a double emigration of smolts—autumn as well as spring. Smolts that are bred artificially are always the produce of ova spawned in November, and these form the spring migration. It is assumed that the later spawned ova form the autumn migration. If this be so, it may explain the mystery of the spring and summer run of fish. It is proved that smolts leaving Stormontfield ponds in the spring have returned to the river as grilses in July of the same year, having increased in weight from 3 to 9 pounds each, the grilse caught on July 1 weighing 3 pounds, and that caught on July 31 weighing 9½ pounds. The smolt would probably weigh about 2 ounces, and the rapidity of growth, without any expense for feeding, should make those who have charge of salmon legislation ponder over the problem of close time.

What, then, becomes of the autumn emigration of smolts? Do they come back as spring salmon? The first run of spring salmon, like the first run of grilse, is small in size. From 8 to 10 pounds would be the average weight of the first run of spring fish. The spring smolt takes three months to return a grilse; the autumn smolt would have five months to return a spring salmon.

We quite agree with Major Traherne that spring fish stay in the rivers to spawn. We also think, from the appearance of the fish, that the early, small spring fish are maiden fish that have never spawned. Are they not the autumn smolts?

But all rivers do not have a run of spring fish. Major Traherne says: "I notice that early ascending salmon are far more numerous in rivers that have an annual close time commencing on or before September 1, than in rivers where the close time commences after that date." This is simply a confusion of cause and effect. It is the early river that causes the early close time, not the early close time that causes the early river. What causes a river to be early? or, in other words, what causes spring fish to run up one river, and not to run up another? Major Traherne replies, the temperature of the river. He contrasts the early arrival of salmon in Loch Naver with their late arrival, by way of the Thurso, in Loch More, and he says that the River Naver, being fed by a large, deep loch, is warmer than the Thurso, which runs from a small shallow loch; therefore the earlier run of fish into Loch Naver! But the fish run as early up the Thurso River as they do up the Naver River; so this illustration fails. He afterwards refers to the Shin, the Cassley, and the Oykel, all of which rivers empty themselves into the Kyle of Sutherland. He says that the temperature of the water in the Shin—a river flowing from a very large lake—is higher than the temperature of the Cassley, or the Oykel, which are not fed by big lakes; and that this is the reason why the Shin is the only river, running into the Kyle of Sutherland, which produces early salmon. We reply by denying the premise. The Shin may be a rather better early salmon river than the Oykel, but it is not an earlier river. The opening day always finds clean fish in the Oykel, and, this year, from one bank, the Oykel yielded thirteen fish in March. Last year the yield of one bank of the Oykel in April was twenty-three fish; both banks of the Shin yielding thirty fish. Twenty fish in March would be a good yield for the Shin.

But to come back to the question, What causes a river to be early? Certainly it is not the absolute temperature of the river. On the north and east of Scotland the rivers are early, on the west coast they are late. The temperature of the rivers on the west is higher than that of the rivers on the north and east. Contrast the rivers Oykel and Inver. The former rises in the eastern slopes of Ben More in Assynt, and is fed in March and April by the melted snows. It has not any big lock as a reservoir, and in March is often frozen over. The Inver runs out of Loch Assynt at the western foot of Ben More. Little snow lies on the western side of the hill, and Loch Assynt is large and deep. The water of the Inver is higher in temperature than the water of the Oykel. The rivers lie opposite to one another in Sutherlandshire; the Oykel, icy cold in the spring, running east; the Inver, much warmer, running west. The cold river is an early river; the warm river is late. Major Traherne is therefore wrong when he says that the high temperature of a river makes it early. We say that the relative temperature of the river to the sea into which it empties itself determines the run of the salmon. If the temperature of the river closely approximates to the temperature of the sea the fish will run, no matter how cold both river and sea may be. On the west coast the sea is so warmed by the Gulf Stream that the rivers on that coast, although positively warmer than on the east coast, are, relatively to the sea, colder, and they are accordingly late rivers.

The relative temperature of the air and the water has a great effect, too, upon the feeding of the salmon. Major Traherne says: "I never expect to meet with a

blank day in the coldest weather, if I know there are fish in the river." A cold mist coming on will always prevent fish from rising. On a fine April day, when the sun is bringing down snow water, the time to take fish is after the sun has warmed the river, but before the snow melted by the sun about the sources of the river has had time to run down and chill the water. In both cases it is a question of the relative temperature of the air to the water.

"Do salmon feed in fresh water?" is one of the questions the author asks. He answers it in the affirmative, as he cannot believe that fish rush at spinning baits, eat prawns, and chew up a bunch of lob-worms simply to gratify the angler's love of sport. It is difficult, indeed, to understand how the theory of salmon living for months in fresh water "on his own fat, which has been accumulated while feeding in salt water"—as Dr. Francis Day puts it—could have been accepted by him, or by the late Frank Buckland. Why are good salmon rivers bad brown trout rivers? Simply because the salmon feed on the trout.

The question of close time Major Traherne says "is the key to the situation; in other words, to the adjustment of the various claims of netting proprietors and anglers, as the prosperity of our salmon fisheries, and the increase or decrease of a most valuable article of food depends in great measure upon the periods fixed to suit each river." This means that the proper adjustment of close time to each river will divide the clean fish fairly between the upper and lower proprietors, and will also provide abundant spawning fish to fill the beds upon the upper waters. At present the weekly close time in England and Scotland, extending from 6 p.m. on Saturday to 6 a.m. on Monday, is too short to enable fish to run past all the nets on many of our rivers; the upper nets sweeping in on Monday morning most of the fish that left the salt water on Saturday night. Again, the rod fishing is kept open too late. We have constantly seen gravid fish taken in October, out of which the eggs or milt ran when the fish were landed—fish that were neither able to fight, nor fit for food. Late in the season the gravid fish will take any bait as voraciously as the kelts in early spring, and the angler is able to state that he killed his six or eight heavy fish a day. After being kippered they are just eatable, and that is the best that can be said for them. On the other hand, with each of the female fish—and most of the fish killed at the end of the season are hen fish—perish some 20,000 eggs fully developed. All that Major Traherne says about the weekly close time, as well as about the closing of the fishing in the autumn, deserves careful consideration.

AN ELEMENTARY TEXT-BOOK OF GEOLOGY.

An Elementary Text-book of Geology. By W. Jerome Harrison, F.G.S. (London: Blackie and Son, 1889.)

IT is well known that there are certain things, which, like reading and writing, come by nature, such as the driving of a gig, and the management of a small farm. These every man can do. And till lately it seems to have been very generally held, that, when a man or woman had shown by repeated failure that he or she was hopelessly incompetent to earn bread in any other way, there was nothing to forbid him or her from opening a school for small children: the laying of the foundations of an education was such a simple matter that it was within the reach of everyone. It looks also as if the writing of an elementary text-book on a scientific subject is very generally held to be an equally easy task, at least the bounteous profusion with which such books are showered upon us would appear to point to such a conclusion. But anyone who has tried to teach or to write a book that shall be used for teaching purposes, knows only too well that it is with the beginner and in the elements of his subject that the real difficulty lies. And besides the inevitable obstacles to success which from the nature of things he must meet with here, there are to be taken into account others of a more artificial kind. An elementary text-book must be cheap; neither author nor publisher can be expected to be wholly indifferent to profits, and only cheap books pay in science; but, setting this consideration aside, it is of the first importance that the work should be within the reach of the largest number possible of buyers. Cheap, and therefore small and sparingly illustrated. So here arises the first difficulty. What to leave out in the text and how far illustrations may be dispensed with.

Before these questions can be answered, the author must make up his mind what end he proposes the book shall be made to compass. For there are two most distinct purposes which a text-book may be intended to serve. It may be designed to educate the reader; or it may be put together in order to help him to get through an examination. And for books of the first kind there are two classes of readers to be provided for: some will never go beyond the elements of the subject; for others the text-book is only the first step on a journey which will lead them on through all the details and ramifications of its subject. But the needs of both classes are at the outset very much the same. Both want a basis, broad and flat in its simplicity, on which they can plant their feet firmly; not a surface so rough and jagged with complicated details that they are bewildered to know where, or whether anywhere, a secure foothold is to be found on it. For both the aim of the book must be to give fibre and sinew to the mind, not to pack into it a miscellaneous assortment of useful and interesting facts; the mastery of the book must involve not the mere exercise of memory, but the continuous use of observation and the logical faculty.

In every branch of science there are certain parts which are eminently fitted to serve these ends, and other parts which will most effectually defeat them if introduced into an elementary work. Now, in the Presidential address to the British Association at the recent meeting at Newcastle the objects which ought to be exhibited in a Museum intended for popular instruction were most lucidly marked off from those that ought not: an almost identical classification will divide those parts of a scientific subject which ought to find a place in an elementary text-book from those that ought not. In the same address an emphatic warning was given against overcrowding the cases. Equally must the writer of a text-book be on his guard against congested sentences or chapters.

Here, as in all education, the course of instruction, if it

is to be of any value for mental discipline, must lead up from the simple to the complex, from the particular and concrete to the general and abstract. To start with the nebular hypothesis in geology may claim to be taking things in their historical order, but is like giving meat to a baby of three months old. To lay before the beginner a familiar object such as a lump of sandstone or limestone; to show him how to pull it to pieces and find what it is made of; to give him reasons for the belief that it has not existed from the beginning of all things, but is a naturally manufactured product; to drive him to rummage brook, river, pond, and sea, the whole field of outdoor nature, in hopes of finding some similar product now in process of manufacture,—some such treatment as this at the outset would seem to be the way to lead a beginner on to use his hands, his eyes, and his reasoning faculties—in a word, to educate him. And at this stage only well ascertained facts, and conclusions on the soundness of which no doubt can be thrown, ought to be introduced; incomplete observations and experiments, inferences which are no more than likely, all provisional and speculative hypotheses, and all controversial matters, ought to be kept carefully in the background. We do not trust a youngster among quicksands and shaking bogs till much walking over sound ground has given him sturdy legs, sure feet, a quick eye, and sound judgment. There is a bit of advice given in the preface to the book now before us, which is not likely to do much harm because it certainly will not be followed by those for whom the book is written; but one shudders to think of the mental chaos that would result from reading every book or article on geology which can be bought or borrowed, the controversy on the Taconic System included. To encourage so omnivorous an appetite is not according to knowledge.

The limits of an article will not allow of more than the fringe of the subject being just touched upon; but enough has been said to show what seem to be the things to be striven after and the things to be avoided in a book on elementary science which aims to educate its readers.

The other kind of text-book is necessarily constructed on a totally different principle. The author's aim is to satisfy the requirements of a syllabus or code; lucky it is if he is a slave to only one, and does not vainly struggle to meet the demands of many. The reader must be fortified against every possible form of question which the ingenuity of the examiner can devise without going outside the prescribed limits; and as that ingenuity is boundless, the number of such questions must be legion. Hence arises the necessity of packing into a small compass an endless variety of subjects, with the result that only a few words can be spared for each. Each also, instead of standing out crisp and sharp with an appropriate heading to call attention to it and emphasize its importance, shares with two or three others, with which it may have only a remote connection, the cramped quarters of a single sentence. What a risk there must be in such a case that matters of great moment may be passed by unheeded! Even in a crowd we may stumble on interesting folk, but it is not in a crowd that intimate acquaintance or lasting friendships usually begin.

There is another evil in books of this kind; they foster the dangerous belief that there are short cuts to learning—a notion welcome enough in this age of hurry and unrest, when everything is to be done quickly, well also if you can, but quickly at any cost.

An amusing illustration of the educational value of the ordinary text-book may perhaps be allowed a place here. A girl, sharp enough to be worth taking pains with, came to me for assistance in the preparation for her examination. She was happy in the possession of a text-book which professed to give all the information which her syllabus required on I know not how many branches of science. She was just beginning the section on chemistry and was much exercised as to the meaning of chemical symbols. I was able to remove her difficulties, and to send her away hopeful that further progress would be easy and rapid. The latter it certainly was, for at the end of a week she came again with a beaming face; she had finished chemistry, and made some way in meteorology. I naturally demurred to her getting her geology in this fashion, and substituted for the geological section of her book a well-known primer. She repaid me and showed her appreciation of what scientific writing ought to be, by declaring that this was as good as a story-book.

But it would not be fair to take the precious compendium from which, but for a lucky accident, this girl would have derived all her knowledge of science, as a fair sample of the average text-book. On many even of the second class it is possible to look with qualified satisfaction, and, though the work before us must be placed in this class, it is good of its kind. There is life and spirit in it, and here and there its points are happily put. No one who reads it attentively can fail to get from it information which not only will be serviceable in examinations, but may be used as a stepping-stone to further progress in its subject. But I should like to call the attention of the author to a few points in which there seems to be room for improvement.

The exigencies of space demand that there should be no repetition in a book of this kind. But there is more than one case in which our author says over again what has been already said on a previous page. For instance, on pp. 71 and 72 we have much that has been previously given in chapter ii. The amount of dissolved matter in the Thames is stated twice over, on p. 11 and again on p. 73. Other cases might be quoted. The general arrangement of chapter viii. does not seem to be commendable: it is hard to see why such simple matters as ripple-marks, rain-pittings, and sun-cracks should come after the more complicated structures of foliation and faulting; what would seem the natural arrangement, of beginning with the simple, is absolutely reversed. The term current-bedding is used and partially explained on p. 22, but we do not find a full definition till p. 45.

A few cases of incomplete information and even of looseness of statement may be noted. In speaking of the consolidation of sediment by pressure, only the weight of the overlying rock is mentioned on p. 18. Whether glaciers move solely by the force of gravity, as is implied on p. 76, is to say the least a moot point. The description of fire-clay as "a fairly pure variety of clay, *containing but little water*," can hardly be said either to be accurate or complete. Marl is not clay mixed with *lime*. It is surprising to find among so many really good illustrations the time-honoured section across the Jura on p. 42, which only deserves to be preserved as about the most successful

effort that was ever made to represent things as they are not. The two paragraphs on contorted strata and inverted strata which follow are instances of the congestion which is unavoidable in text-books of the second class. It is impossible in so small a space to give the prominence which it deserves to the conception of horizontal thrust and compression, and very few readers would realize, from the few words devoted to them, the surprising character of the thrust-planes of the Scotch Highlands. It is scarcely fair to magnetite to say that it *sometimes* exhibits magnetic properties, and ferrous carbonate does not give a green, blue, grey, or purple colour to rocks (p. 70). One and only one more objection will I urge. There is a lamentable absence of geological sections. No verbal descriptions will suffice to convey to anyone, let alone a beginner, clear notions of the geological structure of a country without illustrative sections. The reader of the present work will gather from it the parts of the country in which the various formations are seen at the surface, but he will come away with very few notions as to the lie of the rocks. I cannot help feeling that the "imaginary scenes" during the several geological epochs might be usefully replaced by a set of geological sections.

A. H. GREEN.

THE FLORA OF DERBYSHIRE.

A Contribution to the Flora of Derbyshire; being an Account of the Flowering Plants, Ferns, and Characeæ found in the County. By the Rev. W. H. Painter. 8vo, pp. 156, with a Map. (London: George Bell and Sons, 1889.)

DERBYSHIRE is much the most interesting of our midland counties from a botanical and physico-geographical point of view. Geographical botanists, following Watson, divide the surface of Britain into two regions of climate—a lower or agrarian region, in which the cultivation of cereals and the potato is practicable, so far as climate is concerned; and an upper or Arctic region, in which no cultivation is possible. The agrarian region is divided into three zones, and whilst in Surrey, Hampshire, Wiltshire, and Kent, only one of these three zones is represented, in Derbyshire, Shropshire, and Cheshire, we get all three of them, and a greater area of super-agrarian zone in Derbyshire than in any other midland county. The plants of Britain, botanical geographers divide into two principal groups—the southern types, which have their head-quarters in Central Europe, and the boreal types, which have their head-quarters in Northern Europe, and grow only upon high mountains further south. The southern types are to the northern as six to one—about 1200 species against 200; but less than 50 species reach the midland counties. In Derbyshire we get a declination of surface from mountains nearly 2000 feet high down to a low level, so that it shows better than any other county how, in the centre of England, the boreal and austral elements of the flora meet and mingle together.

The whole area of the county is a little over a thousand square miles—about one-sixth that of Yorkshire. The Pennine chain, the backbone mountain-ridge of the north of England, extends for some distance into Derbyshire forming the watershed between the streams that flow into the German Ocean and the Irish Channel. We may divide the county into two unequal halves by a line that runs across it from west to east, from Ashbourne to Duffield. South of this line, with Derby in its centre, is a level tract underlaid by new red sandstone, with a flora like that of Leicestershire, Nottinghamshire, and Warwickshire. North of this line, all the rocks are Palæozoic, and the level gradually rises. The Carboniferous limestone occupies the lower levels about Castleton, Matlock, and Buxton. This is much the most interesting part of the county, and the best known to strangers, the region of lead mines, caverns, and romantic narrow dales, girdled by high cliffs of limestone: Miller's Dale, Monsal Dale, Ashwood Dale, Chee Tor, Chatsworth, Haddon Hall, are all familiar names alike to botanists and lovers of fine scenery; and Dovedale, Bakewell, and Rowsley are classic ground to anglers. The market-place at Buxton is over 1000 feet above sea-level, so that Buxton is on a par, so far as plants go, with Dundee or Aberdeen. The heights of Abraham, over Matlock, are about the same height above sea-level as the town of Buxton. About Castleton and Buxton the limestone reaches a height of 400 or 450 yards, and with it many plants of the lowlands; for instance, *Epilobium hirsutum*, *Galium cruciatum*, *G. verum*, *Lamium purpureum*, and *L. incisum*, reach a higher level than anywhere else in the country. On the whole, the botany of the Derbyshire limestone tract is most like that of Ribblesdale, Airedale, and Wensleydale. Above the limestone in the Peak country, and around Buxton and Castleton, there is a considerable thickness of shale and millstone grit. The flora of these higher levels is poor and monotonous, but we get the cloudberry (*Rubus Chamæmorus*) on Axe-edge, the bearberry (*Arctostaphylos Uva-ursi*) on the moors round the head of the Derwent, and the whortleberry (*Vaccinium Vitis-idæa*) in several places about Buxton and Glossop. East of all these is an area of coal-measure country, the flora of which seems to be very poor, and to resemble that of the country round Huddersfield, Sheffield, and Halifax.

Mr. Bagnall has already shown, in the *Journal of Botany*, that Mr. Painter's numerical analysis, on p. 4 of the "Derbyshire Plants," classed under their types of distribution, needs material revision. Out of 532 plants universal in Britain, Mr. Bagnall's estimate, founded on Mr. Painter's detailed list of species, is 486 species for Derbyshire. In all probability, most of the other 46 species will be found if they are carefully sought; but, of the 599 species which represent the characteristically southern element in the British flora, there are 238 species in Derbyshire, or less than half. I cannot understand why the figure of the Germanic, or characteristically south-eastern plants, which is 127 for Britain as a whole, 38 for North Yorkshire, 26 for Northumberland and Durham, should be as low as 14 for Derbyshire. Out of 201 boreal British species, there are 39 in Derbyshire against 104 for the Lakes, 93 for Northumberland and Durham, and 76 for North Yorkshire. What Watson called the intermediate type, is a very interesting group; they are concentrated in the north of England, and I suspect that the principal reason of this is, that they are Montane plants with a preference for limestone. The

comparative figures are: 37 species for Britain as a whole, 33 for North Yorkshire, 21 for the Lakes, 21 for Northumberland and Durham, and 16 for Derbyshire. The total number of Derbyshire plants is 782 species out of 1425 recorded for the whole of Britain.

Mr. Painter's note (pp. 5-10) on the bibliography of the botany of Derbyshire is full and satisfactory. Unfortunately, many of the early records contained in Pilkington's "Derbyshire," and copied into the old "Botanist's Guide," are evidently inaccurate. But a great many trustworthy records, which stand on the personal authority of Mr. H. C. Watson and Mr. J. E. Bowman, are contained in the "New Botanist's Guide," of which Mr. Painter seldom takes notice. The curious *Achillea serrata*, a plant not known anywhere in a wild state, which Sir J. E. Smith describes and figures, in "English Botany," from the neighbourhood of Matlock, he does not mention at all.

As Mr. Painter explains in his preface and indicates in his title, his work is not put forward as a complete record of the flora of the county. It is not likely that much that is new will be found in the limestone tract and on the gritstone moors, but the exploration of the coal tract and level new red sandstone country is still very incomplete. A full and adequate flora of a county so interesting would be a very acceptable contribution to the literature of botanical geography. J. G. B.

OUR BOOK SHELF.

Science of Every-day Life. By J. A. Bower, F.C.S. (London: Cassell and Co., 1889.)

We have here another attempt to simplify the acquirement of a knowledge of some of the elementary facts of science, but though there is much to be commended, some points certainly require revision. With reference to the well-known experiment in which bits of straw, wood, or cork come together when thrown into a basin of water (p. 22), the author has fallen into the common error of ascribing the effect to gravitation instead of to surface-tension. If a few wax-lights or other things not wetted by water be added, it will be found that a substance which is not wetted is *repelled* by a substance which is, and that only "birds of a feather flock together." Again, with young students, loose or incomplete statements cannot be too carefully guarded against; the statement on p. 59 that 15 pounds or 30 inches of mercury is "equal to a square inch column of air to *whatever height* it may extend" is of this class.

The book is apparently intended more especially for the young people's section of the National Home-Reading Union, but it is hardly likely that many of the branches will be furnished with the necessary apparatus for the experiments. The ground covered includes the properties of matter, and the physics and chemistry of air and water.

Elementary Physics. By M. R. Wright. (London: Longmans, Green, and Co., 1889.)

In this book Mr. Wright has added to the more elementary part of his work on sound, light, and heat, the leading facts of other branches of physics, so as to form a general introduction to physical science. The subject is an essentially experimental one, and the author, having learned by experience that a study of facts is the first duty of beginners, very little space is given to theoretical considerations. There is very little that is new, and indeed it is hardly to be expected. Most of the experiments are clearly described and are capable of easy performance, but one or two improvements may be suggested. On p. 4 the student is told to "cut a hole in an iron plate so that a flask filled with cold water just passes," an operation beyond most students, and we see no reason why a piece of card should not do equally well. Again, on p. 6, the making of a thermometer is hardly sufficiently detailed; having made a bulb at one end of the tube, the student is simply told to make one at the other end, but he will certainly not see his way to do this without further assistance. There are no less than 242 diagrams, but, needless to say, most of them have done good service before.

The book is excellently adapted for such a course of instruction as that laid down in the syllabus of alternative physics by the Science and Art Department.

Teacher's Manual of Geography. By J. W. Redway. (Boston, U.S.: D. C. Heath and Co., 1889.)

We have of late heard a good deal on the subject of how geography should be taught, but now we find an author who believes "that less energy devoted to improvement of methods, and a little more to the quality of the material taught, would not be amiss." The author's view of the scope of geography is much broader than that generally accepted, and, in this country at least, the title "physical geography" would be regarded as more appropriate.

The first part of the book consists of "hints to teachers," and very valuable hints they are. Oral instruction and out-of-door lessons are strongly recommended, and the author attempts to make the subject a practical one by suggestions as to the use of the moulding board for representing the various features of a country. The free use of pictures and instructive stories from authentic books of travel, especially with primary pupils, is also recommended.

In the second part, common errors, such as the assertion that "lakes which have no outlet are salt," are corrected. There is also an interesting chapter on the history of geographical names. The book is quite unique, and teachers will find much to interest as well as instruct them.

Notes on the Pinks of Western Europe. By F. N. Williams, F.L.S. Pp. 47. (London: West, Newman, and Co, 1889.)

Last week we noticed Mr. Williams's classified enumeration of all the known species of Dianthus. In the present pamphlet he gives Latin descriptions of, and English notes upon, the species of Western Europe. Out of a total of upwards of 200 species, there are altogether 55 in Western Europe, which are distributed through the different countries as follows, viz. 43 in Spain, 33 in France, 13 in Portugal, 7 in Germany, 5 each in Belgium and Holland, and 4 in England. His descriptions seem to be clear and explicit, and he has worked out carefully the geographical range of each species, but he does not give references either to published figures, or, with few exceptions, to the books and papers in which the plants have been originally described. As a rule, he admits species freely, but he unites the common European *Dianthus Seguieri* with the Chinese and Japanese *D. sinensis*, which is the parent of many cultivated forms. This gives the species a range from Portugal to Japan. Many of the West European forms are so puzzling, and the descriptions are so widely scattered, that it will be a boon both to botanists and gardeners to have them all brought together and worked out on one uniform plan.

American Resorts, with Notes upon their Climate. By Bushrod W. James, A.M., M.D. (Philadelphia and London: F. A. Davis, 1889.)

WHOEVER imagines, from the imposing exterior of this volume, that he will find much information within its covers on American health-resorts, is doomed to disappointment. In most cases he will be as well or better off if he consults a good gazetteer or geographical dictionary. It is true it contains a translation of some chapters of Dr. Woeikof's "Die Klimate der Erde"; indeed, this forms more than one-third of the volume—a singular method of producing an "original" work.

This translation no doubt contains a great deal of technical detail, but there is extremely little in it to help the ordinary inquirer to select a suitable winter or summer resort. If a possessor of this volume desired to obtain, for instance, some accurate and detailed information as to the climate of Southern California and its principal resorts, he would find the whole of this important region disposed of in less than four pages; while one of its most rising resorts, Santa Barbara, is disposed of with fourteen lines at p. 52, and exactly the same number of lines at p. 152; and another, Los Angeles, gets less than ten lines. No references to meteorological observations, and no climatological details of any kind, are contained in these extremely meagre accounts. In other parts of the book, seven or eight health-resorts are disposed of in a single page (pp. 33, 37, 44). Less than three pages are devoted to Florida and all its resorts. Again no meteorological details of any kind. Denver is disposed of in eight lines, Colorado Springs in a like number, and Salt Lake City in two lines.

It is scarcely necessary to deal seriously with a book put together in this fashion.

Idylls of the Field. By Francis A. Knight. (London: Elliot Stock, 1889.)

WITH the papers in this dainty volume readers of the *Daily News* are already familiar. In spirit and style they closely resemble the papers included in the same author's "By Leafy Ways." Mr. Knight has a genuine love for the poetic aspects of Nature, and in these "Idylls," as in his previous book, he gives many a vivid sketch of scenes and incidents by which he himself has been impressed. The text is illustrated by a number of photogravures from drawings by Mr. E. T. Compton.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A New Logical Machine.

A STRANGE little instrument has been sent to me from Auckland, intended to illustrate the connection between the mathematical laws of thought and the laws of growth.

The machine itself is simple, and consists of two wheels so arranged that, by turning a horizontal one, a perpendicular one is made to revolve. The axle of this latter projects; and on it can be fastened a piece of cardboard. All the magic is in the precise forms of the cards sold with the machine; and of these I must now speak.

Mr. Betts, of the Government Survey, Auckland, devised a mode of stating arithmetically the main laws of thought. (He had not read George Boole's book; but his principle is, in the main, the same as that on which my husband worked.)

Mr. Betts wished to make diagrams which might represent his formulæ to the eye. Having arranged his scales, he proceeded to draw the diagrams; and found, to his surprise, that he was drawing the outlines of various leaves. These leaf-forms have been seen by many artists, who declare that they are not *conventionalizations* but true *simplifications* of leaves occurring in Nature. Mr. Betts next cut these leaf-forms out in white cardboard; cutting slits to mark the growth-lines. When one of these cards is fastened on the axle of his machine, and whirled, bands of colour appear, which differ according to the form of the leaf; but the preponderating colour is green.

When Mr. Betts told me of this by letter, I confess I hardly believed his account; but he has now sent me a machine and some cardboard leaves, and several friends have seen the colours.

Although I understand Mr. Betts's main principle, and am sure that it is identical with my husband's, I will not attempt to explain it, my object being to induce mathematicians here to put themselves in communication with this extraordinary mathematical logician, who, not knowing the calculus of Newton, has supplemented his deficiency by inventing a calculus of *form*, which is so far like in principle to that used by the Creator, as to have received from Nature the consecration of *colour*.

I have, of course, seen the colours; but, having bad sight, I distrusted my own impressions, till I had heard many persons, more fortunate than myself in this respect, describe what they saw.

The address is, Benjamin Betts, Esq., Milton Street, Mount Eden, Auckland, N.Z. MARY BOOLE.

103 Seymour Place, Bryanston Square.

Lamarck *versus* Weismann.

MR. WALLACE'S note with the above title in NATURE (vol. xl. p. 619) contains an illustration of a kind of reasoning that is so common with the post-Darwinians (I know of no other concise expression to designate this class of thinkers) that I desire to call attention to it. His remarks are *àpropos* of the twist in the skull of the flat-fishes, and of Dr. Lankester's comments on the explanation of its origin offered in his book "Darwinism." Mr. Wallace has, as it appears to me justly, ascribed the rotation of the eye of these fishes to the "transmission of a series of slight shiftings of the eye acquired in successive generations by the muscular effort of the ancestors of our present flat-fish" (Lankester, in NATURE, vol. xl. p. 568). This, observes Lankester, pointedly, is "flat Lamarckism." Now Mr. Wallace explains that he has added the following language, which he thinks negatives the explanation cited by Dr. Lankester; "those usually surviving whose eyes retained more and more of the position into which the young fish tried to twist them." Mr. Wallace then says that the "survival of favourable variations is even here the real cause at work."

In the three sentences cited from Mr. Wallace, we have the whole question at issue between the post-Darwinians and the neo-Lamarckians in a nutshell. We have stated the "origin of the fittest" and its probable cause; the "survival of the fittest"; and the *non sequitur* of the post-Darwinians closely following. I point expressly to the words of Mr. Wallace, that the "survival of favourable variations is even here the real cause at work," as containing the paralogism (as Kant would say) which constitutes the error of post-Darwinian reasoning. That survival constitutes *a* cause is clear enough, since from survivors only, the succeeding generations are derived. But it is strange that it does not seem equally clear, that if whatever is acquired by one generation were not transmitted to the next, no progress in the evolution of a character could possibly occur. *Each generation would start exactly where the preceding one did, and the question of survival would never arise*, for there would be nothing to call out the operations of the law of natural selection. *Selection* cannot be the cause of those conditions which are prior to selection; in other words, a selection cannot explain the *origin* of anything, although it can and does explain survival of something already originated; and evolution consists in the origin of characters, as well as of their survival.

The attempt to produce variations by mutilations, or by abrupt modifications of the normal conditions of plants and animals, is not likely to prove successful, as it has evidently not been Nature's way of evolving characters, although some well-authenticated instances of such inheritance are on record. And the fact that we have not as yet an explanation of inheritance, may be applied with equal force against any and all theories of evolution that have been entertained. E. D. COPE.

Philadelphia, November 3.

Galls.

IN his suggestive paper on Prof. Weismann's theory, Mr. Mivart says, while alluding to the formation of galls, "It would be interesting to learn how natural selection could have caused this plant to perform actions which, if not self-sacrificing (and there must be some expenditure of energy), are at least so disinterested."

Mr. Mivart here strikes what has always appeared to me one of the most important facts in organic nature with reference to the theory of natural selection. I have always so considered it, because it seems to me the one and only case in the whole range of organic nature where it can be truly said that we have unequivocal evidence of a structure occurring in one species for the exclusive benefit of another.

Moreover, the structure is here a highly elaborate one, entailing not only a drain on the physiological resources of the plant (as Mr. Mivart observes), but also an astonishing amount of morphological specialization. Indeed, the latter point is so astonishing, that when we study the number and variety of gall-formations in different species of plants—all severally adapted to the needs of as many different species of insects, and all presenting more or less elaborate provisions for ministering to such needs—it becomes idle to doubt that, if such cases had occurred elsewhere and with any frequency in organic nature, the theory of natural selection would have been untenable, at all events as a general theory of adaptations and a consequent theory of species. But seeing that the case of galls is unique in the relation which is now before us, it becomes reasonable to attribute the formation of galls to the agency of natural selection, if there be any conceivable manner in which such agency can here be brought to bear.

Now, although it is obvious that natural selection cannot operate upon the plants *directly*, so as to cause them to grow galls for the benefit of insects, I think it is quite possible to suppose that natural selection may operate to this end on the plants *indirectly through the insects*, viz. by always selecting those individual larvæ the character of whose excitatory emanations is such as will best cause the plant to grow the kind of morphological abnormality that is required.

This explanation encounters difficulties in some special cases of gall-formation, which I will not here occupy space by detailing; but as it is the explanation given in a course of lectures which I am at present delivering to the students here, I should like to take the opportunity, which Mr. Mivart's paper affords, of asking whether anybody else has a better explanation to offer.

GEORGE J. ROMANES.

Edinburgh, November 18.

"Modern Views of Electricity."

YOUR reviewer (p. 5) takes rather high ground wherefrom to criticize a confessedly popular and expository book; and some of the charges of vagueness—as, for instance, that I do not definitely specify the velocity with which electricity travels in a given current—strike me as rather out of place, seeing that the same charge might be made against the treatise of Clerk-Maxwell. A want of definiteness about the constitution of the ether I must perforce admit; and I can hardly be surprised at your reviewer's want of sympathy with my struggles to convey to non-mathematicians some idea of the tendencies of modern inquiry, when I find that he thinks it "open to question whether attention has not of late years been too much diverted from the condition of the charged bodies in the electric field to that of the medium separating them."

But it is not so clear how, holding this view, he can say that the tentative theory attempted to be explained by me "is in its most important features almost identical with the old two-fluid [action at a distance] theory published by Symmer in 1759"; nevertheless, by taking a few statements from the earlier and introductory portion of my book, and caricaturing them a little, he does manage to make it appear as if the so-called "modern views" were merely a case of reversion to an ancestral type.

However, it is not on these general topics that I break a wholesome rule and reply to a review: it is because I am charged with four or five definitely misleading statements, and it is these I wish to either withdraw or justify.

First, concerning the relation between the Peltier effect and the E.M.F. at a junction. I have argued this matter out fully in the *Philosophical Magazine* for March 1886, p. 269, and have shown that the only "further assumption" needed is this:—*The measure of the E.M.F. at any section of a circuit is the work done per unit electricity conveyed past that section, or,* $dW = QdE$. Until this is disproved I regard it as axiomatic: and, so regarding it, I hold that what I have said about contact E.M.F. is true. My position in the matter is, at all events, perfectly clear and definite, and is fully explained in the *Philosophical Magazine* article referred to, as well as in several others of older date.

Second, as regards tourmaline. I certainly did not *intend* to explain pyro-electricity as due to unilateral conductivity solely, but perhaps my brief statements concerning it on p. 122 might be more cautiously worded so as to avoid any possible misconception.

Third, the "dead-water" argument against electric momentum (p. 103) is not *left* as a valid proof of its non-existence, though it is introduced as at first sight so tending; and all that my critic says against it resolves itself into a question of degree.

The same is true of what he says on the fourth point, concerning Fitzgerald and the Kerr effect; and his assertion that Fitzgerald's deductions do not coincide with the observations of Kerr and Kundt seems to me to convey a much falser impression than my nine-year-old statement (p. 323) to which he objects: "Mr. Fitzgerald, of Dublin, has examined the question mathematically, and has shown that Maxwell's theory would have enabled Dr. Kerr's result to be predicted."

Lastly, my suggested possible account of the Thomson effect (pp. 117, 120, 295), though it does not indeed altogether hold water (as both Prof. Everett and Prof. J. J. Thomson have kindly pointed out to me), breaks down for a reason entirely different from that supposed by your reviewer, who is estimating it only from his own caricature of an ether theory. The real weak point lies in forgetting that the condition required is unequal *impulse*, not simply unequal *force*.

In thus replying to objections raised, I by no means suppose that my critic has made them in any unfriendly spirit. I only feel that he has read the book rather unsympathetically, and (possibly on account of faults in the preface) has regarded it as more scientifically pretentious than its style and object at all warrant. Misleading statements as to matters of fact I have indeed strenuously endeavoured to eschew, and I trust that to very few of them shall I have, in a second edition, to plead guilty.

OLIVER J. LODGE.

November 16.

Geometrical Teaching.

MR. WOODALL has called attention to an evil which, even at the present day, is more extensive and persistent than is generally supposed to be the case by those who imagine that "improved methods of geometrical teaching" are making themselves felt.

It is surprising that such a subject as Euclid, which of all subjects perhaps is best calculated to produce in the minds of young persons an exact method of reasoning, should be so badly taught. There can be, I should imagine, only one opinion as to the method of teaching described by Mr. Woodall, viz. that it is decidedly bad; and even worse, that it is perfectly useless.

It is often objected by this class of teachers that young people cannot be brought to appreciate the intricacies and subtleties of Euclid's propositions, and that, in consequence, if they be learnt at all they must be learnt by heart. But is not this a great mistake? My own experience has shown me that young persons *can* be induced to appreciate and take an intelligent interest in Euclid if it be taught intelligently. This demands some little trouble on the part of a teacher, and I suspect that a large proportion of our bad geometrical teaching is due to the disinclination of the teacher to take overmuch trouble in his work, coupled with the fact that it is often very difficult for him to get over the superstition of his own school-days, that a proposition, if it be learnt at all, must be learnt by heart, without any display of intelligent interest.

It does not seem to me to be necessary, at the outset at any rate, in order to improve the teaching, that the ordinary well-known edition of Euclid should be taken to pieces in order that a new and elaborate arrangement of the propositions may be made out of the fragments, according to some individualistic, arbitrary, or so-called scientific method. Sufficient for the day is the evil thereof. The effective teaching of Euclid may be

conducted upon the old line, so well known to us in Potts and Todhunter; but to make it effective our teachers must be possessed of ordinary common-sense. So long as this is absent, all the elaborate and scientifically improved editions of Euclid's "Elements" in the world will not produce the much-to-be-desired change. Let the teacher go through any edition of the first book of Euclid's "Elements" in a common-sense manner with his pupils, and he will find that, instead of the apathy and general disgust exhibited by them when undergoing the ordinary process of Euclidian cram, there will be a general air of brightness, interest, and intelligent appreciation.

HAROLD WAGER.

The Yorkshire College, Leeds, November 25.

A Brilliant Meteor.

WHILE at my observatory to-night, at 9.37 p.m., I saw the largest and brightest meteor I have seen since November 1880. It became visible near ν Eridani, and disappeared near α Leporis. The colour was a bright greenish blue, and the brightness was twice or three times Venus at greatest brilliancy. It cast a distinct shadow.

J. COCKBURN.

St. Boswells, N.B., November 23.

STAR DISTANCES.[1]

THE festal offering contributed by Prof. Oudemans to the Pulkowa celebration is an especially appropriate one. The incidents of the long parallax-campaign can scarcely be recapitulated without recalling, in connection with the name of Friedrich Struve, the *quorum pars magna fui* of Æneas. He it was who, in Sir John Herschel's opinion (Memoirs R. Astronomical Society, vol. xii. p. 442), made the first real impression upon the problem by showing that not one of twenty-seven circumpolar stars discussed in 1819-21 could possibly have an annual parallax amounting to half a second of arc. Thenceforward, astronomers knew what they had to expect. Sanguine hopes of meeting comfortably large, and properly periodical residuals among ordinary observations, were checked, if not extinguished. The changes of stellar position reproducing, according to the laws of perspective, the movement of the earth in its orbit, were perceived to be on a scale so minute that their satisfactory disclosure lay, for the moment, beyond the range of what was feasible. Success in the enterprise, it was evident, was conditional upon the employment of more perfect instruments than had heretofore been available with a precision and vigilance of which the very idea was absent from all but a few prescient minds. Sir William Herschel seemed to have anticipated the conjuncture when he declared in 1782 the case to be "by no means desperate," although stellar parallax should fall short of a single second (*Phil. Trans.*, vol. lxxii. p. 83). The memorable "triple event," by which, almost simultaneously, at the Cape, at Königsberg, and at Pulkowa, his confidence was justified, is familiar to all readers of astronomical history. Its significance may be estimated from Bessel's admission that, until the yearly oscillations of 61 Cygni emerged from his measures in 1838, he was completely in the dark as to whether stellar parallax was to be reckoned by tenths or by thousandths of a second (*Astr. Nach.*, No. 385).

The value to students of Prof. Oudemans' synoptical view of what has since then been achieved in this direction can hardly be overstated. Not only does he record every individual result worth considering, but the tabulated particulars enable a fair judgment to be formed as to the value of each. There are, indeed, one or two cases in which a note of warning might with advantage have been added. Thus, Dr. Brünnow's small parallax for 85 Pegasi, to say the least, requires confirmation. A perfect *equability* in the mode of observing is essential in such delicate operations; but the Dunsink astronomer was himself conscious of, and noted with his usual care, a slight change, as the series flowed on, in his habit of "bisecting" the large star (*Dunsink Observations*, vol. ii. p. 38). The distance of this interesting binary system can hence scarcely be regarded as even approximately known.

Still less reliable, though for different reasons, are Johnson's measures of Castor, and Captain Jacob's of α Herculis. The parallax assigned to the latter star of 0"·062 relative to its fifth magnitude companion cannot be other than illusory, since the pair, as evidenced by a small, but well-ascertained common proper motion, are physically connected, and must therefore be at virtually the same distance from the earth.

Forty-nine stars, all save one measured within the last sixty years, are included in Prof. Oudemans' list. The exception deserves particular mention. Samuel Molyneux erected at his house in Kew Green in 1725, a zenith sector by Graham, with which he began, in combination with Bradley, a set of observations for parallax on γ Draconis. The same star had, in the previous century, been similarly experimented upon by Robert Hooke with something of a dubious success. The well-known eventual issue of Molyneux's observations was Bradley's discovery of the aberration of light; but they included besides an element of true parallactic change, brought out by Dr. Auwers's discussion in 1869,[1] after it had lain concealed among them for 142 years. The eye and hand must indeed have been faithful thus to record an ebb and flow of change profoundly submerged, at that comparatively remote epoch, in the reigning confusion betwen the real and the apparent places of the heavenly bodies.

A light-journey of sixty-five years (parallax = 0"·05) may be considered the present limit of really measurable stellar distance. Forty of the forty-nine objects so far investigated lie—most of them certainly, a few only probably—within it. Forty stars can thus be located with some definiteness in space—forty among, say, forty millions! The disproportion between our knowledge on the point and our ignorance is so exorbitant that general conclusions seem discredited beforehand, and negative ones at any rate can have no weight whatever. Nevertheless, one remark at least is fully warranted by the evidence.

It is this, that the largest stars are not always those nearest to the earth. For to the narrow category of stars at ascertained distances belong no less than seven invisible to the naked eye, one of them in closer vicinity to us than Sirius, all than Capella, Vega, Arcturus, or Canopus. A cursory view might almost suggest—irrespective of geometrical possibilities—that stellar brightness had nothing whatever to do with remoteness. The legitimate and certain conclusion to be derived from the facts, however, is that the disparities of stellar light-power are enormous. A farthing rushlight is not more insignificant compared with the electric arc than a faint compared with a potent sun. Sirius emits 6400 times as much light as a ninth magnitude star north of Charles's Wain (Argelander-Oeltzen 11,677); our own sun falls nearly as far short of the radiative strength of Arcturus. Inequalities of the same order between the members of revolving systems emphasize this result. Sirius shines like four thousand of its own companions; and the movements of other stars are perhaps swayed by almost totally obscure bodies.

The inference that the apparent lustre of individual stars tells us nothing as regards their distance was already

[1] "Uebersicht der in den letzten 60 Jahren ausgeführten Bestimmungen von Fixstern parallaxen." Von J. A. C. Oudemans. Eine Festgabe zum 50 jährigen Jubiläum der Sternwarte zu Pulkowa. *Astronomische Nachrichten*, Nos. 2915-16.

[1] *Monatsberichte*, Berlin, 1869, p. 630. The result places γ Draconis at a distance of 35½ light-years, but with a very large "probable error" (parallax = 0"·092 ± 0"·070).

drawn by Dr. Huggins in 1866 (*Phil. Trans.*, vol. clvi. p. 393); it has been amply confirmed since, and cannot be too forcibly insisted upon. We are unable to place either an upper or a lower limit to stellar dimensions or intrinsic emissive intensity. Until Arcturus was proved to be immeasurably remote, few would have been disposed to credit the existence of a sun in space at least six thousand times as effulgent as ours is; but we know no reason why Arcturus itself should not be as vastly exceeded by some giant orb at the outskirts of the Milky Way; while we are equally debarred from asserting that among sixth, seventh, twelfth magnitude stars, there may not be found some minute bodies at half the distance from us of α Centauri.

But when we pass from particular to general reasoning, the aspect of the matter changes. No cause has yet been shown why the stars should be exempt from obedience to the "law of large numbers" which provides (as Prof. Edgeworth has ably shown) a clue to other labyrinths of facts. Statistics, it is true, are often misleading, but only when they are wrongly employed. The frequent misuse of a method does not justify its total rejection. And the statistical method is peculiarly liable to misuse. Attempts to get from it more than it will properly give inevitably fail; and what it will properly give are general statements which should only be generally applied. An average result may not be the less instructive because it is by its nature incapable of furnishing specific data.

The stars then *must*, on the whole, decrease in brightness as their distances increase, and they must do so according to an underlying fixed law which will be more and more closely conformed to the larger the number of instances included in the generalization. Each descent of one stellar magnitude represents a falling off in light in the proportion of 2½ to 1; it represents, accordingly, an augmentation of distance in the proportion of the square root of 2½, or 1·59 to 1. Theoretically, that is to say, stars of any given magnitude are 1·59 times more remote than those one magnitude superior, 2½ times (1·59 × 1·59), where the gap is of two magnitudes, and so on. This would be strictly and specifically true if all the stars were equal; but since they are enormously unequal, the rule may be grossly misleading in particular instances, and can only, by taking wide averages, be brought to approximate closely to actual fact.

The determination of individual parallaxes has always, with astronomical thinkers, been subordinate to the higher aim of obtaining a unit of measurement for sidereal space. Hence continual attempts to fix the "average parallaxes" of classes of stars, which, however, remained futile so long as precarious assumptions supplied the place of direct information. Nor could this be obtained until the exigencies of the research had evoked improved means of practically meeting them. The earlier observers chose the subjects of their experiments entirely with a view to their successful issue. Stars likely, owing to their brilliancy, their swift motion, or both combined, to be nearer the earth than most others, were picked out for measurement, with results, each by itself of high interest, but worthless for generalizing purposes. It is only a few years since increased skill in the handling of methods authorized an extension of the range of their application. The first systematic plan for investigating "mean parallax" was proposed by Dr. Gill in 1883, and is now in course of combined execution at Yale College and the Cape. The completion last year of a section of the work enabled Dr. Elkin to deduce an average distance of thirty-eight light-years for the ten first magnitude stars of the northern hemisphere; but it would of course be folly to regard this avowedly "provisional and partial" result as a satisfactory basis for definitive conclusions about the distances of more remote classes of stars. At the most, it makes a useful temporary starting-point for some trial-trips of thought through space. Before long, however, through the exertions of Dr. Gill and Prof. Pritchard, direct measures, not only of all the first, but of most of the second magnitude stars all over the sky, will have been executed; and the proportion between distance and brightness thus established may with some confidence be used as a fathom-line for sounding otherwise inaccessible sidereal abysses.

A. M. CLERKE.

DR. H. BURMEISTER ON THE FOSSIL HORSES AND OTHER MAMMALS OF ARGENTINA.[1]

THIS handsome volume is a continuation of the author's monograph on the fossil horses of the Pampean beds of Argentina, of which the first part was published at Buenos Ayres in 1875, and is stated to have been specially brought out for the Paris Exhibition. The author has, however, not done himself justice as regards the title of this portion of the work, since, in addition to the description of remains of the horses of the Pampean, he also describes and illustrates the osteology of *Megatherium*, *Mastodon*, and *Macrauchenia*, so that a better title for this volume would have been "The Fossil Horses and other Mammals of the Pampean Deposits."

Like the former part, the text of this volume is printed in parallel columns of Spanish and German; and the execution of the plates leaves nothing to be desired, so far as a clear delineation of the essential features of the specimens portrayed is concerned. All the specimens forming the subject of this monograph, are, as we learn from the introduction, preserved in the National Museum at Buenos Ayres, of which the learned author is the Director; and, so far as we may judge from the description and figures, that collection of fossil mammals must be unrivalled in the excellence and completeness of its specimens.

The first section of the work, or that to which the title alone properly applies, is devoted to the horses; and the author commences his description by observing that the *Equidæ* differ from all other Ungulates in that the premolars are larger than the true molars. For the more generalized species of the Pampean deposits, like *Equus principalis* of Lund, Dr. Burmeister adopts the Owenian genus *Hippidium* (*Hippidion*), remarking that these forms are distinguished from the modern horses by the shorter and more curved crowns of their cheek-teeth, which are of a more simple general structure, and also by a difference in the form of the narial aperture, as well as by their shorter limbs and stouter limb-bones. In the

FIG. 1.—Three right upper cheek-teeth of *Hipparion*, *a*, posterior, and *b*, anterior outer crescent; *c*, anterior, and *d*, posterior inner crescent; *e*, anterior, and *f*, posterior pillar.

structure of their upper cheek-teeth the horses of this peculiar South American group make, indeed, a decided approach to the more generalized representatives of the family, such as *Hipparion*. In the latter the anterior pillar of these teeth (Fig. 1, *e*) forms, as is well known, a

[1] "Los Caballos Fósiles de la Pampa Argentina," Suplemento. ("Die fossilen Pferde der Pampasformation, Nachtrags Bericht.) By Dr. Hermann Burmeister. Folio, pp. 65, pls. 4. (Buenos Ayres, 1889.)

subcylindrical column totally unconnected with the anterior crescent (*c*); in *Hippidium* this pillar retains almost the same form as in *Hipparion*, but becomes connected with the crescent; while in the existing horses the same pillar has become greatly elongated in an antero-posterior direction. Further, in *Hippidium* the first premolar, which in modern horses is generally absent, and if present is minute and deciduous, is of very large size, and always persists.

The Pliocene *Equus stenonis* of Europe forms, however, a connecting link in respect of dental characters between the American *Hippidium* and the modern horses; and it is therefore to a great extent a matter of individual opinion whether or no the retention of *Hippidium* as a distinct genus is convenient. A new species referred to *Hippidium* is described from Tarija, in Bolivia. Of more typical horses the author describes additional remains of *Equus curvidens*, *E. argentinus*, and *E. andium*; and he adds to his description a useful word of warning in regard to the many forms of fossil horses from other parts of South America which have been described as distinct species, suggesting that all or several of these may be based merely on individual variations.

In the second section of the volume we have a description of remains of other mammals from the Pampean deposits recently acquired by the Museum at Buenos Ayres. The first of these additions is an entire skull of *Megatherium americanum*, which shows that our previous knowledge was incomplete. This skull formed part of a nearly entire skeleton of a very large individual found in August 1888 on the Rio Salado, but which is as yet but partially disinterred. It shows that instead of the aperture of the nares being bounded superiorly merely by short nasal bones which did not reach within a long distance of the premaxillæ, there was a large prenasal bone extending nearly as far as this point; while there was also a lateral process projecting forward from the upper part of the maxilla into the nasal aperture. This prenasal bone is 4½ inches in length, and it is considered probable that it became united with the nasals in the adult. Still more remarkable, however, is the presence of another ossification extending upwards and backwards from the superior surface of the extremity of the premaxillæ towards the prenasal bone, from which it is only separated by a short interval. These two ossifications, we may observe, are evidently a rudiment of the complete bony arch connecting the premaxillæ with the nasals in *Mylodon darwini*, which was on that account generically separated by Reinhardt as *Grypotherium*; and they serve to support

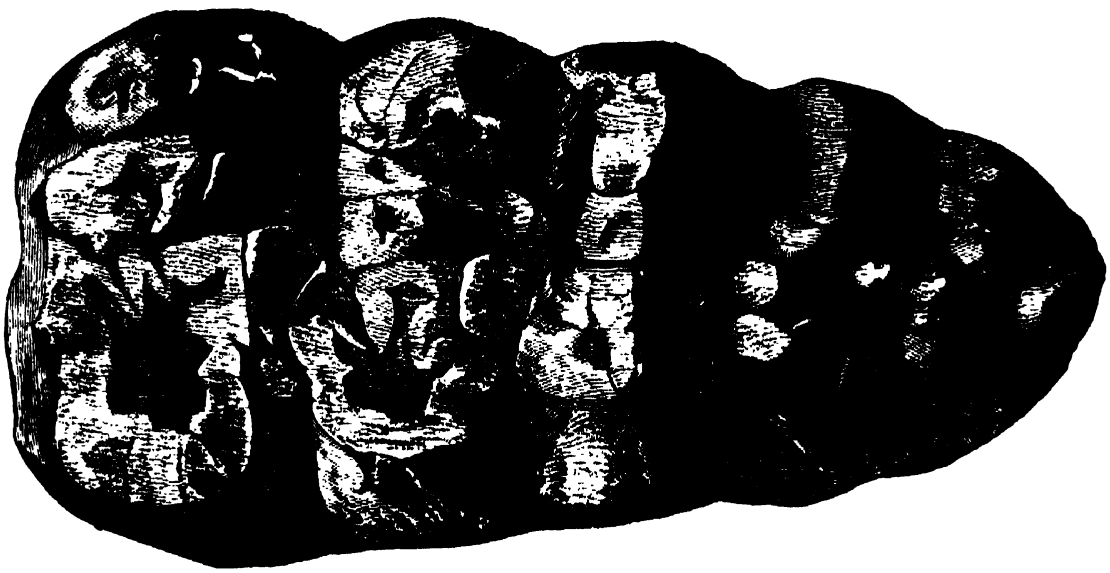

Fig. 2.—The third left upper true molar of *Mastodon humboldti*; from the Pampean of Buenos Ayres. Two-thirds natural size.

Prof. Flower's view that the last-named species is not separable from the genus in which it was originally placed.

The author next proceeds to the consideration of the skull of that species of *Mastodon* which he terms *M. antium*. No mention is made of the earlier name *M. cordillerum*, which appears to be the proper one for this species; and in amending the usual spelling *M. andium* to *M. antium*, one cannot help wondering why the same course was not adopted in the case of *Equus andium*. The object of this part of the work is to show that the reference by the late Dr. Falconer to *M. cordillerum* (as we will call it) of mandibles from Texas, furnished with long tusks is incorrect, and that this species really had, like its near ally *M. humboldti*, a mandibular symphysis of the same general type as that of the elephants, without any tusks at all in the adult. Figures are given of an immature and of an adult skull with the mandible *in situ* to support this redetermination. Dr. Burmeister then proceeds to institute a comparison between *M. cordillerum* and *M. humboldti*, in which he states that, although very similar, a careful examination shows very clearly the distinctness of the two forms. Here we may observe that it is to be regretted that no comment or reference is made to the notices and figures published by Falconer and other English writers in reference to these forms; but perhaps the real explanation of this omission is that the libraries at Buenos Ayres are not so well stocked as those of London. According to our author, *M. cordillerum* is the smaller of the two species; the length of the mandible from the condyle to the symphysis being 75 centimetres against 85 centimetres in *M. humboldti*; the last dimension agreeing with the British Museum skull of that species originally described by Falconer in *M. andium*. Falconer's observations as to the more complicated structure of the molars of *M. humbolti* are in the main confirmed. A small specimen of a last upper molar referred to this species in the British Museum is (with the permission of Dr. Woodward) figured in the accompanying woodcut, to show the complexity of the crown, in which the valleys are much blocked by accessory tubercles. In the early stage of wear of this specimen imperfect trefoils of dentine are shown only on the inner columns; but when more worn trefoils would evidently also appear on the outer columns. In the well-worn upper molar of *M. cordillerum*, represented in Plate x., Fig. 5, of the work before us, the absence of a distinct trefoil on the outer columns, which Falconer mentioned as one of the distinctive features of this species, is well shown. Dr. Burmeister further observes that the molars of *M. cordillerum* are characterized by their blackish enamel, and the brown or

reddish colour of the dentine; while in *M. humboldti* the whole of the crown is of a yellowish or white hue, with darker roots. These distinctive colours are very noticeable in many of the specimens in the British Museum, which have been respectively referred to the two species in question.

The work concludes with descriptions of the remains of two species of the remarkable Perissodactylate genus *Macrauchenia*, viz. the typical *M. patachonica* of Owen, and *M. paranensis*, originally described by Bravard as *Palæotherium*. Of the former species an entire skeleton is figured, and the author concludes that the genus is, on the whole, most nearly allied to *Palæotherium*, although the skull presents some remarkable resemblances to that of the tapirs. It appears, moreover, from the presence of muscular impressions on the cranial bones, that the nose formed a short proboscis, as in the latter group. The author also gives us an elaborate description of the teeth, which are undoubtedly of a Palæotherioid type. It is further observed that in the author's opinion there appear to be no grounds for generically separating *M. paranensis* and the smaller *M. minuta* from the typical genus; and the author concludes his volume with some remarks on the proposal of Dr. F. Ameghino to regard the former as the type of the genus *Scalibrinitherium*, and to adopt the name of *Oxydon[to]therium* for the latter.

The above appears to be the gist of Dr. Burmeister's new contributions to our knowledge of the wonderful Tertiary fauna of South America, which he has done so much to enrich. And we congratulate him on the results of this his latest work, and especially on the excellent illustrations by which it is accompanied, since the want of such aids to a right comprehension of the text forms such a great drawback to the work hitherto published by other contemporary South American writers on the same subject.

R. L.

NOTES.

IN his speech at Nottingham on Tuesday evening Lord Salisbury made a most important reference to the subject of what is called free education. He said:—"There is another question which we have heard a good deal discussed, and that is with regard to what has been, in my opinion, improperly termed free education. I should rather call it assisted education, because I do not know that anybody, however extreme his views, would desire that all the inhabitants of this country, whether rich or poor, whether capable of paying for the education of their children or not, should enjoy free education for those children at the cost of the Chancellor of the Exchequer. On the other hand, I have before expressed the opinion—I expressed it four years ago, before the two last general elections, at Newport—that by making education compulsory, by forcing the people to send their children to school whether they ask it or not, you were incurring a certain obligation to relieve the burden of that compulsion, where the circumstances of the parent were such that it was too heavy for him to bear. We believe that considerable progress in that direction may be made. We have already introduced measures to that effect in Scotland. I believe that with perfect consistency with sound principle, and merely recognizing the fact that where you enforce a duty upon a man you are bound to make it as easy for him as you can—I believe that it will be possible considerably to extend that principle in England, and very greatly to relieve the difficulties of the working man in that respect. But allow me to say that I consider the question as to its rapidity, and as to its progress, to be a question for the Chancellor of the Exchequer. If he has got the money I have no doubt he will do it, but if he has not got the money he will not. But it is an object to which I believe a great deal of the money of a Chancellor of the Exchequer may very fairly be applied." The Government is to be congratulated on the pledge thus given to consider the matter.

THE Royal Society will hold its anniversary meeting on Saturday. After the meeting the Fellows will dine together.

ON Tuesday the degree of D.C.L., *honoris causâ*, was conferred in Convocation, at Oxford, upon Mr. Alfred Russel Wallace. Prof. Holland presented him for the degree, and dwelt upon his labours as a naturalist in Brazil, the Malay Archipelago, and elsewhere; upon the now famous doctrines elucidated by him, and upon the relations between him and Mr. Darwin, reflecting equal honour upon both.

A CONFERENCE, called by the National Association for the Promotion of Technical Education, was held in the Manchester Town Hall on Tuesday. About 300 delegates were present from the different technical schools and associations throughout the Kingdom. The chair was occupied at first by the Mayor of Manchester, and subsequently by Mr. Rathbone, M.P. General Donnelly was present to represent the Science and Art Department, South Kensington. Sir Henry Roscoe, M.P., Sir Edmund Currie, Mr. A. H. D. Acland, M.P., and Mr. Mather, M.P., were among those present. The discussions related to the question of the working of the Technical Instruction Act, 1889. A report was read by Sir Henry Roscoe, showing that the Act was being adopted partly or wholly in a large number of towns throughout the Kingdom. The meeting will do great good, and we shall refer to it next week.

ACCORDING to a circular which has recently been sent to the leading physicists, electricians, and others interested in the history of English science, it is proposed to establish a Gilbert Club, the inaugural meeting of which has been convened this day in the rooms of the Society of Arts at 4.30 p.m. The object of the Club is to do justice to the memory of the illustrious President of the College of Physicians who was in the possession of, and was actually carrying on, the true experimental method of scientific inquiry at a time when Bacon was only talking and writing about it. There can be no doubt that the claims of William Gilbert, of Colchester, have been to a great extent overshadowed by the fame of the renowned Lord Chancellor, and it is much to be regretted that we have not had handed down to us more of the results of Gilbert's labours than are to be found in his celebrated work "De Magnete," published in the year 1600. Such as it is, this work may, however, be justly regarded as the earliest English scientific classic, and its author must be recognized as the first truly philosophical investigator in the now all-important subjects of electricity and magnetism. The Club has been organized for the object of bringing out an English edition of "De Magnete" as nearly as possible in the style of the original folio edition, and to arrange for a befitting celebration of the tercentenary of this work in the year 1900. To quote the circular:—"The publication of 'De Magnete' not only marked an epoch in the science of magnetism, but constituted the absolute starting-point of the science of electricity. It has been hitherto a reproach to British electricians that they too little recognized the merits of the founder of the science." The preliminary list of members already includes the names of Sir William Thomson, Lord Rayleigh, Prof. Tyndall, Sir John Lubbock, Prof. Rücker, Prof. Lodge, Mr. Preece, Prof. Reinold, Prof. Perry, Prof. G. Forbes, Prof. D. E. Hughes, Sir F. A. Abel, Sir F. Bramwell, Sir Douglas Galton, Sir H. Mance, Colonel Festing, Captain Abney, Prof. Carey Foster, Prof. W. G. Adams, Prof. J. C. Adams, Prof. Roberts-Austen, Prof. Thorpe, Prof. G. H. Darwin, Prof. Liveing, Prof. Dewar, Prof. W. N. Shaw, Prof. Poynting, Prof. Ray Lankester, Mr. Crookes, Mr. J. Hopkinson, Mr. Glazebrook, Mr. G. J. Symons, Dr. J. H. Gladstone, Dr. B. W. Richardson, Prof. Victor Horsley, Mr. Latimer Clark, &c.

DR. QUESNEVILLE, the French chemist, died on November 14, at the age of eighty. He took his degree of doctor of

medicine in 1834, having studied chemistry under Chevreul. In 1840 he started the *Revue Scientifique*, a monthly periodical, which he afterwards called the *Moniteur Scientifique*. This periodical came to an end last month, Dr. Quesneville explaining that the task was rendered too severe by the infirmities of old age.

THE chemical laboratory, presented to the Stalybridge Mechanics' Institute by the late Mrs. Margaret Platt, was formally opened last week. The laboratory, which has been provided at a cost of about £600, was projected by Mrs. Platt—who always took a great interest in Stalybridge and its social and educational welfare—shortly before her death. Unfortunately she did not live to see the completion of this valuable addition to the work carried on by the institution, but her representatives have observed Mrs. Platt's wishes in every respect. The laboratory is fitted with all necessary appliances for the practical study of chemistry. At present there are twenty-two students undergoing a course of instruction.

THE ceremony of cutting the first sod on the site of the International Exhibition which is to be held in Edinburgh next year took place on Saturday last. The Lord Provost, who presided, said they were all aware that the Forth Bridge was to be opened soon, and a large number of scientific people would be present on that occasion. Therefore, it seemed a most opportune occasion to show a collection of matters connected with electricity such as had never been gathered together before. They had promises from all parts of the world, and the little difficulties that were in the way with the London Chamber of Commerce had, he believed, all been got over, and now there would be a unanimous feeling throughout the whole of the electrical world that this Exhibition should be made a great success.

THE Christmas lectures at the Royal Institution (adapted to a juvenile auditory) will this year be given by Prof. A. W. Rücker, F.R.S., on electricity. They will begin on Saturday, December 28.

THE following are the Science Lectures to be given at the Royal Victoria Hall during the month of December:—December 3, "Snakes and Snake-poison," by Dr. W. D. Halliburton; December 10, "A Visit to the Banks of the Rhine," by Mr. A. Hilliard Atteridge; December 17, "My Experiences in Cape Colony," by Prof. H. G. Seeley, F.R.S.

COUNT SALVADORI has just published the first part of a supplement to his famous work on the Birds of New Guinea and the Molucca Islands, entitled "Agguinte alla Ornitologia della Papuasia e delle Molucche." The present part consists of sixty-four pages, and relates to the *Accipitres*, *Psittaci*, and *Picariæ*, which were the orders treated of in his first volume of the "Ornitologia." During the seven years that have elapsed since the completion of Count Salvadori's work much has been done. Hunstein, who was an excellent collector, and whose untimely death by a tidal-wave in New Britain is deplored by all naturalists, made some valuable explorations in the Horse-shoe Range of the Astrolabe Mountains, and discovered the wonderful new Birds of Paradise, *Paradisornis rudolphi*, *Astrarchia stephaniæ*, and others. Mr. H. O. Forbes explored the same district, and also procured some novelties, and the adventurous expedition of the last-named naturalist and his wife to the Tenimber Islands is quite one of the exploits of the last decade. Mr. C. M. Woodford has likewise added many new species to the known avi-fauna of the Solomon Islands, so that altogether Count Salvadori has had ample material for his supplementary notes. Besides giving abundant information respecting the additional synonymy and geographical distribution of the members of the three orders treated of in the present supplement, the author adds twelve species of *Accipitres*, fourteen *Psittaci*, and nine *Picariæ*. Count Salvadori thinks that *Astur shebæ* of Sharpe from Guadalcanar is the same as *A. pulchellus* of Ramsay from Fauro, but as both species are represented in the British Museum such a mistake in identification is scarcely likely. He separates the Timor Laut *Astur*, supposed to be identical with *A. albiventris* of Bouru, as a new species, *Astur*, or as he calls it *Urospizias polionotus*. Several doubtful points among the Parrots, Count Salvadori will probably be able to settle when he comes to England and examines the series of skins in the British Museum. Of Cuckoos, he describes two new species (*Cacomantis arfakianus* and *Lamprococcyx poliurus*), and *Tanysptera meyeri* is a new Kingfisher.

IT is proposed that a meteorological station shall be established at the Bermuda Islands after the completion of the telegraph service between them and Nova Scotia. Many vessels leaving Halifax, the masters being unaware of the approach of storms from the West Indies, are dismantled before they have been out three days. The establishment of the proposed meteorological station would, therefore, be of great value, and the Canadian Government has willingly consented to bear half of the cost.

WE have received vol. xi. of "Aus dem Archiv der Deutschen Seewarte," containing the report of that institution for the year 1888. Great activity is displayed in the collection of observations at sea, not less than 740 logs and abstract journals having been received during the year, and synoptic charts of the North Atlantic have been published for four quarters, ending with August 1885. Several meetings have been held at the Seewarte for the purpose of preparing an atlas of clouds, and the work is now about to be published. In addition to several treatises on terrestrial magnetism, the volume contains (1) an article by Dr. Vettin on the volume of air flowing into or out of barometrical minima and maxima in different seasons, as determined from the direction, height, and velocity of clouds, observed at Berlin during the years 1882–83, in connection with the data afforded by the daily weather charts published by the Seewarte. (2) The rainfall conditions of Germany from 1876–85, by Dr. H. Meyer. The author has not been content with using the usual monthly values, but has investigated the daily observations from the original documents. He finds that periods of two to four rainy days are more frequent than the same periods of dry days. Periods of five or more wet days are more frequent on the coast than in the interior, but longer dry periods are more probable here than on the coast. On the coast the probability of a change from dry to wet is greater than a change from wet to dry, while the reverse holds in the interior. Periods of twenty or more wet days have occurred only in Western Germany, while the same periods of dry days are of the rarest occurrence in any part of the country.

THE Pilot Chart of the North Atlantic Ocean for November shows that, during the early part of the month of October, an extensive area of high barometer occupied the central regions of the North Atlantic; its position varied from day to day, but on the 12th its centre moved south of the 40th parallel, and low pressure prevailed over nearly the whole of the Transatlantic routes until the 19th. At this date an area of high barometer passed eastward from the American coast, and slowly traversed the ocean, reaching the British Isles towards the end of the month. Several storms occurred north of the 50th parallel, and also along the Transatlantic routes east of the 50th meridian. Two cyclones of great violence occurred off the Atlantic coast of the United States. One developed quite suddenly on the 14th, 150 miles east of Hatteras, and after lingering there for four days, started off rapidly to the eastward; the other storm, which was central off the Carolina coast on the 23rd, was remarkable for its violence and its increase of energy after reaching the Gulf Stream. Several other storms of minor importance occurred on that coast during the month. Comparatively little fog was

experienced, but ocean ice prevailed in considerable quantity to the eastward of the Straits of Belle Isle, and to some extent on the Grand Banks, in marked contrast with what is usually experienced at this time of year.

A CURIOUS dwarf Japanese tree, *Thuja obtusa*, brought by Mr. Samuel from the Paris Exhibition, was exhibited at the meeting of the Royal Botanic Society on Saturday last. The specimen was only some two feet high, and was stated to be about 130 years old. The secretary said that these dwarf Japanese trees were good illustrations of the power of endurance of plants and trees under severe ill-treatment. In the Society's garden may be seen several specimens of the common oak, between forty and fifty years old, yet only some ten or twelve inches in height. They were planted as an edging to a flower border, and kept clipped like the old-fashioned box.

THE greatest depth found by Captain Spratt in the Western Mediterranean basin was between Sicily, Sardinia, and Africa (about 10,600 feet). Recent measurements in the eastern basin by Commander Magnaghi, of the Italian Navy (*Riv. Sci. Ind.*) have yielded, as maximum depth, 13,556 feet, between the Islands of Malta and Candia.

AT the annual meeting of the Severn Valley Field Club, at Wellington, in January last, Dr. Callaway, the President, was asked to prepare a report of the year's proceedings with a shorter account of the work of the preceding year. These reports have now been issued, and show that a resolute effort is being made to promote a taste for geology and natural history in the district, and to make the Field Club something better than a picnic society.

COLONEL WOODTHORPE recently delivered, at Simla, a lecture on the Aka Expedition of 1883. It may be remembered that this tribe, which inhabits the hills north of Assam, owing to some forest disputes and a supposed interference with their trade in rubber, seized two of our forest officers and carried them off. To recover these men, a small expedition was despatched, under the command of Colonel Woodthorpe. The Aka houses are built on piles raised above the ground, with a large space at one end, where the children play. The dress consists of a tunic of Tibetan cloth, and trousers, reaching to the feet, made of thin white material. Long trousers are worn to keep off the *dam-dum*, a troublesome little fly or mosquito. Bows and arrows and knives, with blades easily detachable from a bamboo handle, are the chief weapons. The barbs of the arrows are dipped in aconite, and are so treated that, when any attempt is made to pluck out the arrow, the barb breaks off and remains in the wound. The poison is so deadly, that even a buffalo usually falls, after running a few yards, when he has been struck by one. Some of the superstitions of the Akas are curious. If a river runs between an Aka's house and his burying-place, his soul can never go home after death. This inability of the spirit to cross water is, however, overcome, and, every year, Akas may be seen stretching a string across the stream that divides the grave from the house of the departed. The ghost can easily cross when the slightest foothold is given him.

IT is sometimes said about old trees (*e.g.* an old lime in the new Gardens at Potsdam) that the present branches are properly roots; and it has been reported that trees may be planted, and will grow, in the inverted position. A scientific inquiry into this matter has been made by Herr Kny, in Germany, taking a number of plants of wild vine (Ampelopsis) and ivy, about 3·5 metres high. In 1884 he planted these with both ends in the ground; and in the spring of 1885, after the tops had rooted, he cut the arch at its highest point. In the first year two of the plants died, but the others (twelve vine and fourteen ivy) grew vigorously, and were still alive this last spring. To test the extent of the inversion, he cut slips from the inverted plants, and planted them in a greenhouse, some with their natural, and some with their artificial upper end uppermost. It appeared that the callus, from which the roots spring, was formed at both ends, but more readily at the naturally lower end, whether this was above or below, in the experiment. Herr Kny considers that, notwithstanding several years' successful culture, the inversion was not thoroughly completed. He proposes to continue his investigation, and invites people who have gardens to make like experiments with other plants, recommending willows, poplars, and roses.

THE latest Colonial Report from Basutoland contains a statement by Sir Marshall Clarke on education in that State, written at the request of Lord Knutsford. The total amount granted by the Government during 1888 for educational work was £4581 amongst four missions, of which £2900 went to the Paris Evangelical Missions. The number of schools receiving Government aid was 100, with a nominal roll of 4053, and an average attendance of 3480. The education offered is, for the most part, of an elementary character, suitable to a people of agricultural pursuits, whose children are withdrawn early for labour in the field. It consists of reading and writing in Sesuto, and a little elementary arithmetic and English. A higher education is offered at the missionary centres. The number of schools under direct European supervision is 21, with about 1400 pupils on the attendance roll. At Morija, the head-quarters of the Paris Evangelical Missionary Society, the training school affords a sound English education, the staff being composed of well qualified Europeans. There is an interesting girls' school at Roma, the chief Roman Catholic mission station, where the pupils are instructed in carding, spinning, weaving, and the elements of dressmaking, as well as in English and Sesuto. Schools receiving Government aid are, from time to time, inspected by Government officers, who check the attendance rolls, examine the pupils, and, at the end of the year, submit reports from each district.

MR. H. Y. L. BROWN, the Government Geologist of South Australia, returned to the Angle Pole head camp from his exploration trip to the Musgrave Ranges on October 7. Accord-to the *Colonies and India*, the route was *viâ* Cootanoorina and Arkaringa Creek to Glen Ferdinand, a trigonometrical depot. The exploration extended among the ranges to longitude 131° E., latitude 26° S. Mr. Carruthers, the Government Trigonometrical Surveyor, starting from the depot, will continue the survey towards the western boundary, and expects to return in January. The Government Geologist returned *viâ* the River Alberga, striking the telegraph line at the Angle Pole.

FROM the Report of the Ceylon Survey Department for the past year, which has just been issued, it appears that when the calculations of the northward running chain of the 13-inch triangulation were completed, it was found that the computed distance between the two stations at Delft Island differed from that of the Indian system to such an extent as to show a considerable error, probably in the Ceylon work. The resulting error is too small to be appreciable on maps even of the largest scale, but, from a geodetical point of view, the outcome of so much work extending over a large number of years is disappointing. In order to verify the previous work, Colonel Clarke purposes carrying at an early opportunity a new system of triangles along the west coast, utilizing as many as possible of the old stations. A tentative scheme for the triangulation of the west coast has been drawn up, and when an officer is available, he will be sent to inspect the country, and report on the feasibility of the scheme. In consequence of the incompleteness of he diagrams and other records, the construction of a new series of diagrams, in which will be inserted the information gained

from an exhaustive examination of the record books, will be commenced. In the past year sixty-one sheets were scored under the superintendence of the Trigonometrical Assistant, each representing an area of 13·6 miles by 8·8 miles, and containing in all 1687 fixed stations. He has also prepared an elaborate map of the island, showing sheet line distances.

THE Report for the past year on the mining and mineral statistics of Canada, by Mr. H. P. Brumell, of the Dominion Geological Survey, has been received in this country. The total value of the production of minerals of all kinds for the year was $16,500,000—an increase of 1,500,000 as compared with 1887, and 6,000,000 against 1886. Coal is the largest mineral product of the Dominion, the value of last year's yield amounting to $1,098,610, as against $1,178,637, in 1887, and $1,330,442 in 1886. The decrease in the yield of gold has been anticipated for some years. Copper was mined to the value of $667,543, and these figures will in all probability be doubled this year, in view of the rapid development of the Sudbury and Lake Superior Mines. The asbestos yield amounted to $255,007, and the phosphate production shows an appreciable increase.

THE Smithsonian Institution has issued a "Preliminary Catalogue of the Shell-bearing Marine Mollusks and Brachiopods of the South-Eastern coast of the United States," by W. Healey Dall. The volume includes admirable illustrations of many species.

WE have received the sixty-second part of the first division of the "Encyclopædie der Wissenschaften," and the fifty-fourth and fifty-fifth parts of the second division of the same work (Breslau, Trewendt). The first of these three parts is a contribution to the hand-book of botany included in this Encyclopædia; the second and third conclude the seventh volume of the Encyclopædia's Dictionary of Chemistry.

A NEW series of well crystallized salts, ammoniacal selenites, are described by M. Boutzoureano in the current number of the *Annales de Chimie et de Physique*. Most normal selenites are found to be readily soluble in strong ammonia, and the solutions on evaporation either in the air or *in vacuo* deposit crystals of ammoniacal selenites. Four of these interesting salts have been studied in detail, those of zinc, cadmium, copper, and silver. Ammoniacal zinc selenite, $ZnO.SeO_2.NH_3$, is obtained by dissolving neutral zinc selenite, $ZnO.SeO_2$, a salt which crystallizes in rhombic prisms, in strong ammonia at the ordinary temperature. On allowing the solution to spontaneously evaporate, crystals of the ammoniacal salt are deposited in the form of fine long prisms capped by domo-prisms belonging to the rhombic system. The crystals are insoluble in water, which appears to exert no action whatever upon them. They are also unchanged by heating to 100° C., but when heated in a sealed tube the selenious oxide is reduced by the hydrogen of the ammonia with evolution of water vapour and sublimation of selenium. On ignition they are completely converted to zinc oxide. Acids readily dissolve the crystals even when largely diluted with water. The constitution of the salt appears to be

$$Zn\begin{cases} O \\ O-Se-O \end{cases}\!\!\!>N\ H_3.$$

Normal cadmium selenite, $CdO.SeO_2$, is also soluble in ammonia, and the solution leaves on evaporation white rhombic crystals of an ammoniacal cadmium salt, $CdO.SeO_2.NH_3$, analogous to the zinc salt. These crystals are likewise unattacked by water, and are stable at 100°. They also give off water and vapour of selenium when heated in a sealed tube. The most beautiful salt of the series, however, is the ammoniacal copper selenite. Copper forms a normal selenite of the composition $3(CuO.SeO_2).H_2O$, which crystallizes in small green monoclinic crystals. These crystals readily dissolve in ammonia, forming a deep bluish-violet solution, which on slow evaporation in the air yields magnificent blue crystals of the ammoniacal salt belonging to the triclinic system. The salt is found to contain one molecule of water, and is represented by the formula $CuO.SeO_2.NH_3.H_2O$, the constitution being probably more nearly expressed in the following manner,

$$H_3\equiv N\begin{cases} CuO-OH \\ SeO-OH \end{cases}$$

Unfortunately these fine crystals soon alter in contact with air, losing their water and ammonia and becoming covered with a green coating of basic copper selenite. Water has apparently no action upon them, but in reality there is a surface action, the coating of basic selenite thereby formed preventing any further decomposition. In a similar manner silver is found to form an ammoniacal selenite, the crystals belonging, like those of the copper salt, to the triclinic system. They are anhydrous, $Ag_2O.SeO_2.NH_3$, and are blackened by exposure to sunlight. Thus the series is seen to be a very well defined one, the members consisting of normal selenites combined with one molecule of NH_3, generally anhydrous, but occasionally, as in case of the copper salt, containing water of crystallization.

THE additions to the Zoological Society's Gardens during the past week include a Barbary Ape (*Macacus inuus* ♂), a Saker Falcon (*Falco sacer*) from North Africa, presented by Captain Augustus Kent; a Malbrouck Monkey (*Cercopithecus cynosurus* ♂) from West Africa, presented by Dr. Messiter Lang; two Fieldfares (*Turdus pilaris*), British, presented by Mr. J. Young, F.Z.S.; a Golden-naped Amazon (*Chrysotis auripalliata*) from Central America, purchased; a Moluccà Deer (*Cervus moluccensis*), born in the Menagerie.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m., November 28 = 2h. 31m. 57s.

Remarks.

(1) Sir John Herschel describes this nebula as: Very bright, very large, very much extended, very much brighter in the middle. Dr. Huggins noted, in 1866, that the spectrum was continuous, but pointed out in his remarks that this was not to be understood to mean more than that, when the slit was made as narrow as the feeble light permitted, the spectrum was not resolved into bright lines. Further observations are therefore required, for it may be that slight brightenings in the apparently continuous spectrum were overlooked in the early observations. The case of the nebula in Andromeda indicates that, in some of the nebulæ of this class, bright carbon flutings may be superposed upon the continuous spectrum, in which case they will not be very obvious. The carbon flutings seen in the spectrum of the flame of a spirit-lamp are convenient for comparison in an observation of this nature.

(2) This is a typical star of Group II. Dunér describes it as superb and brilliantly developed, the bands 1–9 being perfectly visible. The star therefore affords an opportunity of observing the bright carbon flutings and checking their positions. If they

are very bright, the compound structure, as seen in the spectrum of a spirit-lamp or the base of a candle-flame, may be looked for. The star falls in species 9 of the subdivision of the group, and is accordingly of about mean condensation. Dark metallic lines will probably be found to make their appearance about this temperature, and the presence or absence of *b*, D, or other lines should therefore be noted.

(3) Vogel classes this with stars of the solar type, but is doubtful whether it does not belong to Group II. It is most likely that it is at an intermediate stage—either a late stage of Group II. or an early stage of Group III. There are evidently traces of some of the dark flutings, and it is suggested that the distinguishing numbers of these and the relative intensities of the lines should be noted. The observations made by Prof. Lockyer and myself seem to indicate that the bands in the red are the most persistent as the temperature increases.

(4) According to Gothard this is a star of Group IV., and the usual observations are required.

(5) This is classed with stars of Group VI. in Dunér's catalogue, but it is stated that the type of spectrum is rather doubtful. Like the star given last week, it may possibly be intermediate between Groups V. and VI., and similar observations are suggested.

(6) This is a variable star which will be at its maximum on November 30. Gore gives the period as 281·2 days, and the range as 8 at maximum to < 11·5 at minimum. The spectrum is of the Group II. type, and the suggestions made for the observation of R Tauri (see p. 68) apply equally in this case. It may be further suggested that the spectrum be observed for some time after the maximum, special attention being given to the fading out of the carbon fluting in the green (517, a little more refrangible than *b*) relatively to the other bright spaces.

(7) Gore gives the period of this variable (maximum on December 4) as 276 days, and the range as 8·6 to < 13·5. The spectrum and colour have not yet, so far as I know, been recorded, and midnight observers may therefore take advantage of the approaching maximum. A. FOWLER.

THE TOTAL SOLAR ECLIPSE OF 1886.—The report of the observations of the total solar eclipse of August 29, 1886, made at the Island of Carriacou by the Rev. S. J. Perry, has been published. The two main questions that required spectroscopic observations to answer them were:—(1) Does the absorption, which produces the Fraunhofer lines, take place mainly in a single layer of the solar atmosphere, or in concentric layers? (2) Does carbon exist in the corona? With respect to the first point, Father Perry thinks that the differences in the length of the lines which he observed before totality on the less refrangible side of *b* seems somewhat to strengthen the view that the selective absorption takes place in concentric layers. During totality a search was made for the two principal bands of the carbon spectrum. The part of the spectrum observed was from about *b* to λ560, but no trace was seen of the carbon bands. Father Perry, however, suggests that perhaps the intensity of the carbon spectrum may vary in each eclipse, and may have some direct connection with the amount of solar activity. Some sketches of the coronal streamers are appended to this report.

Mr. H. H. Turner's report of the observations of the same eclipse, made in the Island of Grenada, has also been received. The following is a list of the lines seen and the order in which they appeared:—

h. m. s.		
7 7 45	...	F line appeared.
7 8 55	...	4923 appeared; very short.
7 11 30	...	4923 and 4933. Immediately after, many lines appeared.
7 12 0	...	Totality.
7 20 50	...	Only F; 4923 and 4933 visible at times.
7 21 45	...	4923 still suspected, and 4956.
7 22 28	...	4956; certainly visible.
7 24 42	...	No line visible.

It will be seen that to some extent these observations lead to the same conclusion as that arrived at by Father Perry.

The corona was examined with a view to the detection of currents, but with a negative result.

PALERMO OBSERVATORY.—The fourth volume of observations made at Palermo has been issued by Prof. Riccò, and covers the period 1884-88. The observations of sun-spots during 1885 show that the limiting latitude in which the phenomena occurred were + 25° and − 30°. Two maxima are indicated by the curve of distribution that has been plotted, both extending from about 10° to 15° north and south of the equator, but the number of spots that have been observed in the latter hemisphere considerably exceeds that observed in the former. The minimum which occurs between these two maxima is in a latitude slightly north of the equator. Generally speaking, faculæ appear to have been equally distributed over the sun's surface. The spectroscopic observations that have been made of solar prominences in different latitudes demonstrate that the reversal of the coronal line 1474K and *b* was considerably more frequent a little to the south of the equator than in any other latitude, and was contained within the limits + 30° to − 30°, following somewhat the same line of distribution as that of spots.

Prof. Riccò has included some fine sunset observations made after the eruption at Krakatão, which support the view that, to a great extent, they were due to the suspension of volcanic dust in the atmosphere. A lengthy series of meteorological measurements, some observation of Nova Orionis, Nova Andromedæ, and various comets, are also contained in this publication.

THE VARIABLE STAR Y CYGNI.—The irregularities before observed in the period of this star have been verified by Mr. Chandler's more recent observations (*Astronomical Journal*, No. 204, October 1889). He finds that the period of the star, which increased by nearly two minutes during 1887 and 1888, is now decreasing at a similarly surprising rate. The reversal appears to have occurred about the middle of 1888, and the average value for the last twelve months has been about 1d. 11h. 56·7m. Assuming this average value for the period of the star, an ephemeris is subjoined. Only alternate minima are given.

PARAMATTA OBSERVATORY.—The Government Astronomer at this Observatory, Mr. H. C. Russell, F.R.S., has collected and arranged in a concise form the history of what has been done in New South Wales for astronomy and meteorology since 1778. The paper may be found in the Proceedings of the Australasian Association for the Advancement of Science, Sydney, 1888, p. 45.

MINOR PLANET 282.—This planet, discovered by M. Charlois, January 28, 1889, has received the name of Clorinde.

COMET DAVIDSON (*e* 1889).—Ephemeris for Greenwich time:—

1889.		R.A. h. m. s.		Decl. ° ′

A NEW VARIABLE STAR IN HYDRA.—Mr. Edwin F. Sawyer, in the *Astronomical Journal*, No. 204, gives observations demonstrating the variability of the star 358 (U.A.) Hydræ, R.A. 13h. 41m. 59s., Decl. − 27° 44′·5 (1875·0). An inspection of the observations that had previously been made of the magnitude of this star indicates fluctuations of about one unit, viz. 7m. to 8m., and the period would appear to be about one year. The star is quite red.

SUN-SPOTS IN HIGH SOUTHERN LATITUDES.—The Rev. S. J. Perry read a paper under this title at the meeting of the Royal Astronomical Society on November 8, in which he drew attention to some remarkable instances which have recently occurred of the appearance of sun-spots at a great distance from the equator. These took place on June 5, June 30, October 8, and October 10 respectively; that of June 30 being especially interesting, as the

spot seen on that occasion attained a latitude of 40°, a circumstance for which there are only a very few recorded precedents. Besides these spots mentioned by Father Perry some much larger groups have also been seen at a less but still considerable distance from the equator. Thus on July 26 and 27 a group was noticed in lat. 24° S., while another and more important group in nearly the same latitude was observed during three successive rotations in August, September, and October. Bearing in mind that the mean distance from the equator of all spots in 1888 was scarcely more than 7°, and in the first five months of 1889, but little more than 5°, these outbreaks in high latitudes become very significant; and taken with the marked increase in number and size of spots during the months of June, July, August, and September, as compared with the earlier part of the year, point to the minimum being definitely passed. If this be so, the period of quiescence has been decidedly shorter, the run down from maximum swifter, and the turn towards recovery sharper than in the preceding cycle. Judging from the form of the spot curve on previous occasions when a short period of minimum has followed a maximum of low intensity, as was that of 1883, we may expect that the revival will be rapid, and the next maximum a strongly marked one.

PROPOSED MEMORIAL OF DR. JOULE.

A PUBLIC meeting was held on Monday in the Mayor's parlour at the Town Hall, Manchester, for the purpose of considering the proposal to erect a memorial of the late Dr. James Prescott Joule. The meeting was convened in response to a memorial influentially signed by residents in Manchester, Salford, and the neighbouring country who desire that the "deep sense of the benefits conferred on mankind for all time, as well as of the great honour which accrues to this district, by the scientific work of the late James Prescott Joule should be marked by the erection of some durable memorial of him in the city." The meeting was very numerously and influentially attended. The Mayor of Manchester presided, and amongst those present were Sir H. E. Roscoe, M.P., Mr. J. W. Maclure, M.P., Dr. Ward (Vice-Chancellor of the Victoria University), Dr. Greenwood (Principal of the Owens College), Prof. Osborne Reynolds, Prof. Munro, Dr. Tatham, Mr. F. J. Faraday, and many others.

A number of letters of apology for absence were read. Lord Derby wrote from London:—

"I cannot attend the meeting on Monday in aid of the Joule memorial, having business here, but I heartily sympathize with the object, and will with pleasure contribute."

Mr. William Mather wrote:—

"When the beautiful simplicity of Dr. Joule's life and character are regarded in conjunction with the world-wide fame his labours have acquired among the greatest intellects of our time, we in Manchester must feel that our late fellow-citizen's memory deserves to be kept ever fresh in our midst by a memorial alike worthy of this city and of the imperishable renown which Dr. Joule has won. Those of us who apply science to industry are deeply indebted for the means through which we work to the original thinkers who put the laws of Nature into our hands with clear definitions as to their purposes. I trust this sense of indebtedness may be felt throughout this district, and that funds may be generously supplied to enable the committee to raise a memorial amply testifying to our gratitude and to our admiration for the late Dr. Joule.

The Bishop of Manchester wrote:—

"I greatly regret that I am prevented by an engagement from attending the meeting in connection with the proposed memorial to Dr. Joule. I think that it would be an honour to any town to be the birthplace and home of the man who first proved the truth of the great principle of the conservation of energy. I most heartily sympathize with the movement which the meeting is called together to initiate, and I shall very gladly give a contribution to any fund which may be to-day established or recommended."

The Mayor, having spoken of the relations between Manchester and science in past times, said the scientific work of Dr. Joule had made the name of Manchester famous throughout the world, not merely as that of a great industrial and trading city, but as a centre of intellectual culture and home of genius. This great man was born in Salford, but he learnt his science as a boy from Dr. Dalton, in George Street in this city. There, he, for a period of nearly half a century, found the congenial society which stimulated his genius. He read many of his papers there; his experiments were performed in this city; and to the end he continued to reside in the suburbs, in a quiet and unostentatious way, his riches truly consisting, not in the extent of his possessions, but in the fewness of his wants. The last generation honoured the memory of Dalton by a statue in marble by Chantrey, which was considered to be one of the most beautiful works of art in the city, and it was suggested that they should show their appreciation of Dalton's great successor in a similar way.

Mr. Oliver Heywood moved:—

"That this meeting desires to mark its deep sense of the benefits conferred on mankind for all time, as well as of the great honour which has accrued to this district, by the scientific work of the late James Prescott Joule, by the erection of a durable memorial of him in Manchester, in the form of a white marble statue."

Sir H. E. Roscoe, M.P., said he felt it a pleasure and an honour in more ways than one to be asked to second the resolution, because, in the first place, he was one of the oldest scientific friends of the man whose memory they had met to honour, and because it had been his privilege not only to become acquainted with his important scientific labours, but to enjoy the friendship of one who might truly be said to have been a typical man of science, the simple straightforward searcher after truth for its own sake and that alone. Another reason was a more personal one. On the occasion of his first public utterance in Manchester, now more than thirty-two years ago, when he read his inaugural address on taking up the duties of the Chair of Chemistry in the Owens College, he drew attention to the great work accomplished by Joule. This was, so far as he could learn, the first occasion on which Joule's work and its importance was brought publicly before a Manchester audience, and he remembered as if it were yesterday being asked by several Manchester friends who this Dr. Joule was of whom he had spoken in such high terms, and what was the great discovery he had made. And then he remembered that, after explaining as well as he could to unscientific people the meaning of the mechanical equivalent of heat and the conservation of energy, he added in joke, in order to impress the matter on minds unaccustomed to deal with subjects scientific, that in the good time coming Manchester would be immortalized, not, as they thought, by being the seat of the cotton trade, but rather as being the place where John Dalton worked out the atomic theory of chemistry, and James Prescott Joule placed upon a sure experimental basis the grand principle of the conservation of energy. Since that time many things had happened, many changes had occurred, and the knowledge of Science and her doings was more widespread. We had acknowledged our indebtedness to Dr. Dalton, and we were now met to consider how we could best do the same for Joule. The memorial which had been presented to the Mayor was of itself proof that Manchester was anxious to recognize merit such as that of Dr. Joule, and to acknowledge that services thus quietly and unostentatiously rendered were sometimes of far greater value to the State than those about which much more was heard. This was not the occasion nor was that the place to enter into an elaborate discussion of Joule's scientific labours. It was sufficient now to remember that, just as Lavoisier, more than a century ago, proved the indestructibility of matter, so Joule nearly half a century ago proved the indestructibility of energy—that we could no more destroy or create energy than we could create or destroy matter. And "thereby hangs a tale"—a tale so interesting that it would take long to tell it; a tale so far-reaching that it concerned every great industry; a tale so important that without it all the modern applications of scientific discovery to the daily wants of mankind could not have been made. The events which formed the incidents in this tale had happened in our midst, and had taken place so quietly that but few had known of their existence. Like many great discoverers, Joule was far in advance of his time; and even the results of his most important research, that on the determination of the mechanical equivalent of heat, met with opposition, and were received with incredulity by men who ought to have known better. Indeed, it was an open secret that when Joule's first paper on this subject, an abstract of which had been read at the Cork meeting of the British Association on August 21, 1843, was presented to the Council of the Royal Society for publication in their Transactions, some of the members of that learned body openly expressed their opinion that the paper was nonsense from beginning to end, that the author, who was a mere amateur, living in some remote and rather uncivilized part of the country, out of the charmed circle of metropolitan and professional science, had been entirely mistaken, because he had, forsooth! neglected the whole question

of friction, and had got hold of an absurd idea that the values of the various so-called imponderables could be expressed in quantitative terms, the one of the other. Fortunately for the credit of the Royal Society, someone more far-seeing than these critics, expressed the opinion that the Council had better take care what it was about, because if they acted on these ideas they might find that they, the highest scientific tribunal in the country, had refused to publish the most important scientific discovery of the century, and one which had already been received with acclamation by all Continental scientific authorities. And so the celebrated paper on the mechanical equivalent of heat was printed, seven years after its first announcement, in the Philosophical Transactions for 1850. But while this, with its immediate relations, was Joule's *magnum opus*, other portions of his work were of scarcely less importance, and to one only of these did he (Sir Henry) wish for a moment to revert, as it touched on a fundamental principle in the science of chemistry, and was therefore specially interesting to himself, whilst it served to show the wide area which Joule's researches covered. On January 24, 1843, Joule read a paper before the Literary and Philosophical Society in their rooms in George Street, hallowed by the memory of Dalton, entitled, "On the Heat evolved during the Electrolysis of Water." The results of this apparently trivial research were of the highest importance, as establishing the heat equivalence of chemical action. Dulong, in France, had already determined the amount of heat evolved during combustion, but he did not compare this with the heat evolved by the same combustion in the battery or elsewhere, and Joule's discovery, described in the above papers, was, that the heat which disappears during separation of the chemical elements was equal to that which made its appearance during their combination, on the principle that action and reaction were equal and opposite. And this was the discovery which established the law proving that chemical action was due to the clashing of the atoms, and that the same laws applied to those atoms singly as they did to them when taken in the aggregate, thus showing that chemistry was a branch of molecular physics. He trusted he had given good grounds for the acceptance by that meeting of the resolution he moved. He would humbly suggest that nothing short of a similar memorial to that erected to Dalton ought to be raised in Manchester in recognition of the labours of Joule. They had statues of Cobden, of Dalton, and of good Bishop Fraser; they would soon have one of Bright. Let them not place Joule in any less conspicuous position, for his work was as glorious as any of theirs. Let us have a marble statue as a companion to that beautiful one of Dalton, by Chantrey, in our Town Hall, and let us have a replica of it in bronze to place on our Infirmary flags, so that all who passed for generations might say, "That is the statue of our great Manchester man of science, James Prescott Joule, who did work in our midst not less important than that of his master, John Dalton, whose statue is hard by; both men were honoured by their contemporaries, and are ever more honoured by us who follow them."

Prof. Osborne Reynolds, in supporting the motion, expressed regret that they had not present with them Sir William Thomson, who fought the battle with Dr. Joule. Sir William had written a letter, in the course of which he said: "Manchester is certainly, of all cities in the world, to be envied the honour of being able to erect a monument to Joule as one of its own citizens." Professor Reynolds also made a statement as to the action which had been taken by the Manchester Literary and Philosophical Society, with whom the proposal for a memorial of Dr. Joule originated.

On being put to the meeting, the motion was unanimously adopted.

Mr. Alderman W. H. Bailey moved the appointment of the following Committee to raise, by public subscription, a sufficient sum to carry the above resolution into effect, viz.:—Chairman—the Mayor of Manchester; Treasurer—Oliver Heywood; Thomas Ashton; the Ven. Archdeacon Anson; Sir William Cunliffe Brooks, Bart., M.P.; Alderman W. H. Bailey; Rev. St. Vincent Beechey; C. H. Bayley; Dr. James Bottomley; William Brockbank; J. H. Buxton; Rev. L. C. Casartelli; Councillor George Clay; R. S. Dale; Prof. W. Boyd Dawkins; Mr. Thomas Diggles; Samuel Dixon, President of the Manchester Society of Engineers; F. J. Faraday, Hon. Secretary of the Manchester Literary and Philosophical Society; Lavington E. Fletcher; R. F. Gwyther, Hon. Secretary of the Manchester Literary and Philosophical Society; Samuel Gratrix; Principal J. G. Greenwood; William Grimshaw; Charles J. Galloway; Sir W. H. Houldsworth, Bart., M.P.; T. C. Horsfall; Dr. Charles John Hall; Thomas Harker; Henry H. Howorth, M.P.; William W. Hulse; Henry P. Holt; Isaac Hoyle, M.P.; Dr. Edward Hopkinson; Canon Hicks; James Jardine, High Sheriff of Cheshire; W. H. Johnson; Thomas Kay; George King; Thomas Kay; Horace Lamb; Sir Joseph C. Lee; Ivan Levinstein; J. W. Maclure, M.P.; Councillor J. D. Milne; James Cosmo Melvill; Councillor Alexander M'Dougall, Jun.; Robert Montgomery; Dr. Morgan; William Mather, M.P.; Ludwig Mond (V.P. Chem. Soc.); Prof. J. E. C. Munro; Francis Nicholson; Councillor Charles O'Neill; Henry D. Pochin; W. O. Pooley; Sir H. E. Roscoe, M.P.,; Dr. Ransome; Prof. Osborne Reynolds; Henry Slatter; Dr. Schunck; Prof. Schuster; Councillor Dr. Henry Simpson; Colonel Thomas Sowler; William Thomson; Alderman Joseph Thompson; Councillor S. Chesters-Thompson; E. Leader Williams; Professor A. W. Ward; Thomas Worthington; Rev. Canon Charles W. Woodhouse. Convener of first meeting, Prof. Osborne Reynolds. In his remarks in support of the motion, Mr. Bailey said that speaking as an ex-President of the Manchester Society of Engineers he could testify that, however slow many people might have been to acknowledge Dr. Joule's work, the Society of Engineers had never forgotten Dr. Joule's labours and the benefit which those labours had conferred on the engineers of this country and on the industries of the world generally.

The motion was seconded by Colonel T. Sowler and unanimously adopted.

A vote of thanks to the Mayor for presiding and for the use of his parlour, accorded on the motion of Prof. Ward, seconded by Mr. C. Bailey, brought the proceedings to a close.

HOW PLANTS MAINTAIN THEMSELVES IN THE STRUGGLE FOR EXISTENCE.[1]

ORDINARY English scenery, so full of quiet and so suggestive of repose that one may not readily discover signs of a struggle for existence. In tropical scenery these signs are so clear that they have been recognized again and again by every thinking naturalist who has ever visited tropical regions.

Any comprehensive view of the phenomenon of life upon the globe clearly points to the one conclusion that all Nature is in a perpetual state of desperate warfare, and the keynote of this address must be: the utter remorselessness of Nature, the care for self; the absolute disregard for others. In all cases the weakest goes to the wall.

Evidences of Struggle for Existence in the Plant World.

Ficus parasitica. Seed dropped by bird germinates on fork of some tree, *e.g.* the jack fruit (*Artocarpus integrifolia*); sends long root into soil; gradually spreads itself over, and suffocates the unfortunate foster-mother.

Heracleum giganteum. Allowed to seed itself freely. On June 1, 1889, 573 seedlings had germinated; on August 19, 105 remained, the missing ones having been killed by the more vigorous survivors.

Bertholletia excelsa. Fifteen to twenty-four Brazil nuts are contained in each fruit, the fruit being indehiscent. All seeds germinate at once. The most vigorous gets first through a small hole at the top to the open air, and strangles and feeds upon all the rest.

What Plants struggle for.

Plants struggle for two main objects—viz. their own nutrition, and the reproduction of their species by means of offspring, which they leave behind them, and for which they make adequate provision. The two master functions, nutrition and reproduction, often stand out clearly marked the one from the other—*e.g.* in the Talipot palm (*Corypha umbraculifera*), where the period of leaf-bearing is succeeded by the period of fruiting, the latter being accompanied by the final death of the whole plant.

I.—NUTRITION.

Protective Adaptations associated with the mainly Nutritive Organs.

(1) *Mechanical contrivances.* Large forest trees (often 200 feet high) have buttressed trunks, *e.g.* *Canarium commune.*

[1] Abstract furnished by the Author, Prof. Walter Gardiner, of a lecture delivered at the Newcastle meeting of the British Association.

(2) Large leaves in palms (often 14 feet long), tied in at the leaf-base, *e.g. Didymospermum distichum.*

(3) Young buds of many tropical trees hang vertically downwards, so as to expose the least surface to sun, *e.g. Amherstia nobilis.*

(4) *Prickles and spines developed, e.g.* immense leaf of *Victoria regia* is protected from fish, &c., which, in rising from below, might rupture the leaf-tissue.

(5) *Patrols of ants attracted.* Ants provided with home, honey, and food, *e.g. Acacia sphærocephala.* Similarly, *Ipomœa paniculata* attracts ants by racemose glands supplied with definite ducts, two of which are present in each leaf, at junction of blade and stalk.

(6) During the unfolding and growth of the bud, special mechanisms exist. Thus, water-glands occur at the apex of each leaf-tooth (*Saxifraga crustata*), which provide for the escape of the superabundant water sucked up by the root: otherwise the delicate leaf-tissue might be ruptured. In fully developed leaves, on a cold night, drops may be seen escaping from the teeth, *e.g.* balsam (*Impatiens Balsamina*).

Other glands are also found which secrete mucilage or resin, and so protect the young structures from the effects of excessive drought, *e.g.* ferns (*Blechnum Braziliense*) and other plants (*Clusia sp.* and *Coprosma sp.*).

II.—Reproduction.

The importance of this process is sufficiently obvious from the enormous expenditure of material and energy plants lavish upon it. *Hodgsonia heteroclita*, an extraordinary Indian climber, with its complicated structure and great beauty, opens for one night only, and shrivels up and falls off the next day. *Amorphophallus Titanum*, with its huge inflorescence (the largest in the world), although it takes months to develop, opens only on one night, and then only for a few hours.

α.—Flowers.

(1) *Contrivances to insure fertilization. Masdevallia muscosa* (an orchid) has a sensitive labellum. An insect alighting on it and touching a certain part, is shot into the flower and held a prisoner for some time.

(2) *Protection by means of sticky hairs. Cuphea silenoides* is protected from the attacks of insects by very numerous hairs secreting a gum resin. Many insects are caught, and as many as 7280 may be counted on one plant.

(3) *Plant protected by ants, but flower fertilized by some other insect. Plumbago rosea* has nectaries on the leaves and flower-bracts which attract ants, but the ants are prevented by sticky hairs on the calyx from obtaining access to the honey in the flower.

β.—Seeds and Fruits.

Some plants depend upon the enormous quantity of seeds produced—*e.g.* the wild carrot (*Daucus carota*), which, moreover, sows its seeds by instalments and at different times. Others—*e.g. Voandzeia subterranea*—sacrifice the advantages obtained from a wide dispersal, and depend upon the formation of a few seeds suitably placed in the soil. This plant, in fact, has a mechanism for itself, sowing its own seeds beneath the soil.

For purposes of distribution, *Uncinia brevicaulis* (a sedge) has its fruit provided with small hooks. Small birds, unable to pull out the fruits, are occasionally caught and killed in Jamaica. The fruits of *Stipa pennata*, a grass, bore their way into the ground; and another species, *Stipa spartea*, is even liable to bore its way into the bodies of sheep which are so unfortunate as to come in its neighbourhood (prairies west of Red River Colony).

Contrivances for assisting plants to maintain themselves in the struggle for existence are by no means limited to the higher plants. They exist also in the Fungi and the Algæ, even in the smallest and most microscopic of them. Examples—

I. *Fungi.—Clathrus triscapus*, a Queensland fungus, has an orange-red colour, and the spores smell strongly and are embedded in a sweet mucilage. Colour, scent, and sweetness are the usual advertisements used by the higher plants in connection with pollen dispersion.

Erysiphe Alni. The mildew of the alder has wonderfully hooked fruits, which are possibly carried about by tiny *Acari*, &c. Spores are shot out with some force from the mycelial filaments of the fungus, which attacks and kills flies, *Empusa muscæ.* The ergot *Claviceps purpurea*, at the time of spore-formation, secretes a sugary nectar, so that flies are attracted, and eat and disseminate the spores, just as birds do stone fruits. The spores of *Sclerotina Vaccinii* have an almond smell; are gathered by bees with the pollen, and, being placed on the stigma of healthy flowers, infect the ovary and prevent the formation of seed. In the race between the pollen-grain tube (the rightful owner) and the fungus-spore mycelial-tube, the fungus always wins, and soon spreads itself throughout the tissue of the entire ovary, producing more spores for the bees to gather in mistake again.

II. *Algæ.*—The resting-spores of *Desmids*—microscopically small green Algæ—are frequently covered by a spiny siliceous coat. These probably prevent them from being eaten by *Amœbæ*, *Rhizopods*, &c. The protoplasm of certain cells of *Œdogonium ciliatum* (a fresh-water filamentous Alga) are in the habit of escaping from the cell-wall and beginning life anew. This production of the so-called *swarm-spore* is probably not wholly unconnected with the existence of unfavourable conditions, *e.g. Bacteria* on the cell-wall, deposits of lime on the cell-wall, &c.

Mesocarpus sp., another filamentous Alga, carefully protects its chlorophyll plate from too bright light by turning it so that it shall receive the proper amount only. Should external conditions be exceptionally unfavourable, the protoplasm of the various cells powerfully contracts, and the filament resolves itself into its various constituent units, which sink to the bottom of the river or pond, and there divide up and start afresh.

Special Points worthy of notice.

(1) *Various adaptations by members of the same order, e.g.* the *Cucurbitaceæ* (Cucumber family), in the matter of seed distribution.

In *Schizocarpum filiforme* the seeds escape through a number of slits in the wall of the fruit.

In *Ecbalium elatine* the seeds are violently and explosively shot out in consequence of the sudden rupture of the fruit stalk.

Sechium edule is indehiscent and contains only one seed.

Zanonia macrocarpa dehisces at the apex by means of valves, and lets out winged seeds of extraordinary beauty, which, aided by the wind, can cover very appreciable distances.

(2) *Various adaptations by members of the same genus, e.g.* the *Clerodendrons.*

Clerodendron Koemferi attracts ants by small glands on the leaf and calyx.

Clerodendron fistulosum does the same, but also provides a home for the ants in its hollow stem.

Clerodendron cephalanthum climbs by means of peculiarly modified leaf stalks; has a multiplicity of buds on the axil of each leaf (instead of the usual *one*) and also possesses glands upon its leaves.

Such families as this may well be regarded as accomplished, but at the same time their various contrivances are simply so many marks of a cruel and fierce fight.

(3) *Protective contrivances associated with new annual growth and germination.*

Dioscorea, sp. nov., at each new period of growth produces at first inconspicuous shoots with small leaves which are peculiarly modified into climbing organs. When well established and in the possession of a proper support large green leaves appear.

Hodgsonia heteroclita.—Here again the shoot on its first appearance is dark purple and inconspicuous, with the leaves present merely as scales. It can then scarcely be seen in the tropical forest. Moreover it is a lateral shoot and not the main terminal shoot which it first protrudes above ground. A second lateral and the main terminal are held in reserve against possible accident. When it has reached a certain height, it produces the normal large leaves.

(4) *The accumulation of protective contrivances in the same individual.*

Blumenbachia Hieronymi.—The flower is at first upright and is fertilized in that position. As the fruit develops, the flower-stalk elongates and the fruit is gradually and gently placed upon the ground. Until quite ripe, it is protected by stinging hairs. Later on, these wither, and the fruit is distributed by means of a second series of grapple hairs, which cling firmly to any passing animal.

Strophanthus hispidus.—Fruit, when ripe, opens, and lets out a number of magnificent plumed seeds, which are carried by the wind. The hairs forming the plume are sensitive to moisture and dryness, and are each capable of moving through an arc of 180°. The hairs spread out in dry weather, so that the seeds

may be carried by the wind. They close up tightly when the rains come, so that they may not interfere with the placing of the seed close to the ground and its consequent germination. Sooner or later they break from the seed.

(5) *Particular adaptations contrived for particular classes of insects, &c.*

Ants are caught and killed at Kew by flowers of *Eria stricta* (an orchid). The ants are too large for the flower, but they visit it for the sake of the honey and get caught in the mucilage. Thus both flower and ant suffer.

(6) *The mutual adaptation of plants and animals.*

In some instances animals and plants appear to strive with each other, and, as the one develops a particular protective contrivance, the other likewise adopts some plan to counteract it and annul its efficiency: thus the canari nut (the fruit of *Canarium commune*) develops a hard shell which protects it from most enemies, but the black cockatoo (*Microglossus aterrimus*) reciprocates by developing a wonderfully strong beak, which appears indeed to be developed with a special view to the canari nut. Insects also often imitate parts of plants for their own benefit, *e.g.* leaf insects.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Senate has formally thanked Prof. Sedgwick for his munificent gift towards the new buildings for physiology, and the Museums and Lecture Rooms Syndicate has been authorized to contract for the buildings to be immediately begun.

The following stipends have been augmented: Dr. Gaskell, F.R.S., University Lecturer in Physiology, from £50 to £150; Mr. Gardiner, University Lecturer in Botany, from £50 to £100.

The Special Board for Biology and Geology, recommend the appointment of an additional University lecturer on botany, at a stipend of £100 per annum, after considering a strong appeal for increased teaching power, from the professor and lecturers in the subject. No teacher had practically been added since the departure of Prof. Vines for Oxford, and the regretted death of Mr. Vaizey.

Mr. W. Bateson, the Balfour Student, will give a course of lectures during Lent term, on the study of variation—a distinct and attractive novelty in the biological courses.

SCIENTIFIC SERIALS.

American Journal of Science, November.—This number opens with an interesting address by Mr. R. S. Woodward at the last meeting of the American Association, on the mathematical theories of the earth, in which emphasis is laid on the incompleteness of those hitherto advanced.—From a simple investigation, Mr. R. Hooke concludes that for planetary bodies assumed to have the same surface density (*i.e.* those in which solidification has taken place), the increase of the difference between the mean and surface density is proportional to the increase of the diameter. He tests this by computation of the mean densities of the inner planets from their assigned diameters, and further confirmation is derived from the case of Jupiter's satellites. He also applies the law to computing the ultimate diameters and mean densities (*i.e.* after solidification) of the sun and outer planets.—Regarding Tschermak's theory of the mica group as inadequate, Mr. F. W. Clarke offers the view that all the micas, vermiculites, chlorites, margarite, and the clintonite group, may be simply represented as isomorphous mixtures, every constituent being a substitution derivative of normal aluminium poly- or ortho-silicate.—Mr. E. O. Hovey studies the low trap ridges (some six lines of them) of the East Haven-Branford region in Connecticut; he considers all the trap intrusive, and the western dikes, at least, of later origin than the tilting of the sandstone.—Mr. C. Lea contends that subchloride, and not oxychloride, is the product of the action of light on silver chloride.—There are also papers on an improved standard Clark cell with low temperature coefficient, by Mr. H. S. Carhart; on pseudomorphs of native copper after azurite, from Grant County, New Mexico, by Mr. W. S. Yeates; and on the relation of volume, pressure, and temperature, in case of liquids, by Mr. C. Barus.

THE *American Meteorological Journal* for October contains:—A reprint of Prof. C. Abbe's paper on the determination of the amount of rainfall, read before the recent meeting of the British Association; the object of the paper is to determine the possible errors arising from the different shapes of the rain-gauges, and their height above the sea-level and the ground, &c.—Tornado statistics, by Lieut. Finley: (*a*) for the State of Louisiana, for the thirty-seven years 1852-88,—the total number of storms was only thirty, the month of greatest frequency being April; (*b*) for Texas, for the thirty years 1850-88,—the total number of storms was ninety-six, the month of greatest frequency being June.—Distribution of wind velocities in the United States, by Dr. F. Waldo. In the Eastern States there is a principal maximum and minimum in March and August respectively, with a secondary maximum in autumn, and a winter maximum. The same regularity which exists in the Eastern States does not occur in the other districts, but the region of the Lower Lakes has a little more wind in winter and a little less in summer than the region of the Upper Lakes. He also investigates the secular variation at selected stations, and finds that a period of about nine years is not improbable.—An analysis of a paper, by Dr. H. B. Baker, Secretary of the Michigan Board of Health, on the connection of intermittent fever with atmospheric temperature. For some years that Board has made a special feature of the collection of vital statistics, and publishes valuable reports on sanitary matters in general.

THE *Botanical Gazette* continues to publish valuable original contributions to botanical science, especially in the department of cryptogamy. The August number contains the first of a series of Prof. Farlow's notes on Fungi, and the September number an illustrated paper on the Uredo-stage of *Gymnosporangium*, by Mr. H. M. Richards.—Mr. H. L. Russell also contributes observations on the temperature of trees, illustrated by a diagram; his general conclusion being that the direct absorption of heat is the main cause of the higher temperature of trees, and that it is largely dependent on the character of the bark.

A LARGE proportion of the *Journal of Botany* for August, September, and October, is occupied by the conclusion of Mr. G. Murray's Catalogue of the marine Algæ of the West Indian region, and the continuation of Messrs. Britten and Boulger's Biographical Index of British and Irish botanists.—Mr. W. West's paper on the fresh water Algæ of North Yorkshire is a valuable contribution to a department of botany in which there are but few workers; it is illustrated by a good plate, and contains descriptions of several new species.—Mr. W. H. Beeby contributes a useful account of some of the difficult and critical British forms of *Viola*.—There are other papers of interest, especially to students of British botany.

THE number of the *Nuovo Giornale Botanico Italiano* fo October is entirely occupied by papers read at the meetings o the Italian Botanical Society. They are chiefly devoted to records of local floras, and to descriptions of remarkable teratological forms.—Signor U. Martelli contributes a note on the injury inflicted on the peach by *Taphrina deformans*.

Bulletin de la Société Impériale des Naturalistes de Moscou, 1889, No. 1.—On the origin of the shooting-stars, by Th. Bredichin (in French), being an application of the author's theory of the *comes anomales* to the origin of shooting-stars. The paper will be continued by another on the origin of periodical comets.—On the Jurassic and Cretaceous deposits in Russia; Part 1, on the Upper Jurassic and Lower Cretaceous deposits in Russia and Great Britain, by Prof. A. Pavloff (in French, with three plates). The author's conclusions are to the effect that the Upper Jurassic deposits of Russia are so intimately connected with those of England that a common classification could easily be established. Several fossil species are described and figured on plates, three of them being new (*Olcostephanus blaki*, *O. swindonensis*, and *O. stenomphalus*).—Zoological exploration in the Transcaspian region, by N. Zaroudnoi (in French), being notes of travel, full of interesting information about the nature and fauna of the country.—On a natural way of penetration of superficial water into the depths of the earth, by Stanislas Meunier (in French).—On the *Sparganiæ* of Russia, by K. F. Meinshausen (in German). Ten species are described, two of them (*Sp. ratis* and *Sp. septentrionale*) being new.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, November 6.—Prof. J. O. Westwood in the chair.—Mr. J. W. Douglas sent for exhibition specimens of *Anthocoris visci*, Dougl., a new species taken at Hereford, in September last, by Dr. T. A. Chapman; also specimens of *Psylla visci*, Curtis, taken by Dr. Chapman at the same time and place.—Mr. R. McLachlan, F.R.S., exhibited coloured drawings of a specimen of *Zygæna filipendulæ*, in which the left posterior leg is replaced by a fully-developed wing, similar to an ordinary hind wing, but less densely clothed with scales. Mr. McLachlan also exhibited a female specimen of the common earwig, *Forficula auricularia*, with a parasitic Gordius emerging from between the metathorax and abdomen. He said that it had been placed in his hands by Mr. A. B. Farn, by whom it was taken, and that other instances of similar parasitism by Gordius on earwigs had been recorded.—Mr. W. F. Kirby exhibited a gynandromorphous specimen of *Lycæna icarus*, having the characters of a male in the right wings and of a female in the left wings, caught at Keyingham, Yorkshire, in June last; also a specimen of a variety of *Crabro interruptus*, De Geer, found at Uxbridge.—Mr. W. L. Distant exhibited a male and female specimen of a species belonging to a new genus of *Discocephalinæ*, from Guatemala, in which the sexes were totally dissimilar, the female having abbreviated membranes, and being altogether larger than the male.—Dr. D. Sharp stated that he had observed that in the *Ipsinæ* division of *Nitidulidæ* there was present a stridulating organ in a position in which he had not noticed it in any other Coleoptera—viz. on the summit of the back of the head. He had found it to exist not only in the species of *Ips* and *Cryptarcha*, but also in other genera of the subfamily. He exhibited specimens of *Ips* and *Cryptarcha*, mounted to show the organ. Dr. Sharp also exhibited a number of *Rhynchota*, chiefly *Pentatomidæ*, in which the specimens were prepared so as to display the peculiarities of the terminal segment in the male sex.—Mr. R. Adkin exhibited for Mr. H. Murray, a fine series of *Polia xanthomista*, var. *nigrocincta*, from the Isle of Man, and *Cidaria reticulata* and *Emmelesia tæniata* from the Lake District.—Mr. W. White exhibited a living larva of *Zeuzera æsculi*, and called attention to the thoracic segments with several rows of minute serrations, which evidently assist progression. He stated that the larva exudes from its mouth, when irritated, a colourless fluid, which he had tested with litmus-paper and found to be strongly alkaline.—Captain H. J. Elwes exhibited a number of insects of various orders, part of the collection formed by the late Otto Möller, of Darjeeling.—Mons. A. Wailly exhibited the cocoon of an unknown species of *Antheræa* from Assam; also a number of cocoons and imagos of *Anophe venata* from Acugua, near the Gold Coast; specimens of *Lasiocampa otus*, a South European species, which was said to have been utilized by the Romans in the manufacture of silk; also a quantity of eggs of *Epeira madagascariensis*, a silk-producing spider from Madagascar, locally known by the name of "Halabe." He also read extracts from letters received from the Rev. P. Camboué, of Tananarivo, Madagascar, on the subject of this silk-producing spider.—Mr. H. Goss read a communication from Dr. S. H. Scudder, of Cambridge, Mass., U.S.A., on the subject of his recent discoveries of some thousands of fossil insects, chiefly Coleoptera, in Florissant, Western Colorado, and Wyoming. Prof. Westwood remarked on the extreme rarity of fossil Lepidoptera, and called attention to a recent paper by Mr. A. G. Butler, in the Proc. Zool. Soc., 1889, in which the au hor described a new genus of fossil moths belonging to the family *Euschemidæ*, from a specimen obtained at Gurnet Bay, Isle of Wight.—Mr. F. P. Pascoe read a paper entitled "Additional Notes on the genus *Hilipus*," and exhibited a number of new species belonging to that genus.—The Rev. Dr. Walker read a paper entitled "Notes on the Entomology of Iceland." Mr. R. Trimen, F.R.S., asked if any butterflies had been found in the island. Dr. Walker said that neither he nor Dr. P. B. Mason had seen any during their recent visit, nor were any species given in Dr. Staudinger's list. Dr. Mason said that during his recent visit to Iceland he had collected nearly one hundred species of insects, including about twenty Coleoptera. He added that several of the species had not been recorded either by Dr. Staudinger or Dr. Walker. Capt. Elwes inquired if Mr. J. J. Walker, with his great experience as a collector in all parts of the world, was aware of any land outside the Arctic Circle from which no butterflies had been recorded. Mr. J. J. Walker replied that the only place in the world which he had visited, in which butterflies were entirely absent was Pitcairn Island.

Royal Microscopical Society, October 9.—Dr. C. T. Hudson, F.R.S., President, in the chair.—The President referred to the deaths of the Rev. M. J. Berkeley and Dr. G. W. Royston-Pigott, the former an honorary, and the latter formerly an ordinary, Fellow of the Society.—Mr. Crisp announced that, owing to certain business arrangements, he was obliged to retire from the secretaryship of the Society and from the conduct of the Journal. It was with the very greatest reluctance that he had found it necessary to resign, but there would, he anticipated, be no difficulty in continuing the Journal on its present lines, while he was sure there were many Fellows both able and willing to undertake the duties of Microscopical Secretary.—Mr. John Meade's communication on stereoscopic photo-micrography was read.—The President brought for inspection three photo-micrographs of one of the new rotifers mentioned in his supplement—*Gomphogaster areolatus*.—Mr. E. M. Nelson exhibited a new elementary centering sub-stage which he thought was likely to be useful. It was fitted in the simplest manner by placing two legs under the main stage, and the movement was given to it with the finger; it was very inexpensive, and was only designed to render the ordinary student's microscope of a higher degree of efficiency by providing it with an easy method of correctly centering the condenser and diaphragm.—The President mentioned that *Pedalion* was to be had in many places in the neighbourhood of London about a month ago, where it had not been previously found.—Mr. Ahrens's description was read of his new patent polarizing binocular microscope for obviating the difficulty of using analyzing prisms with the double tube. The inventor uses for an analyzer a black glass prism, set above the objective with a horizontal side upwards. Two faces are symmetrically inclined to the optical axis at the polarizing angle. The pencil is thus reflected at the proper angle, and at the same time divided into two parts, which are then reflected up the two tubes either by prisms or by plane reflectors.—Prof. Abbe's paper, notes on the effect of illumination by means of wide-angled cones of light, was read.—Mr. T. F. Smith read a paper on the ultimate structure of the *Pleurosigma* valve.

Royal Meteorological Society, November 20.—Dr. W. Marcet, F.R.S., President, in the chair.—The following papers were read:—Second Report of the Thunderstorm Committee. This is a discussion by Mr. Marriott on the distribution of days of thunderstorms over England and Wales during the seventeen years 1871–87. Notices of sheet lightning are included in the term "thunderstorms." The years of greatest frequency were 1880, 1882, 1884, and 1872; and the years of least frequency 1887, 1874, 1879, and 1871. Years of greater or less frequency alternate regularly throughout nearly the whole of the period. The average yearly number of thunderstorms is about thirty-nine. The districts with the greatest yearly frequency are the south of England and extreme northern counties, and those with the least yearly frequency are Cheshire, Lancashire, and Yorkshire. The greatest number of thunderstorms occur in July, and the least in February and December.—On the change of temperature which accompanies thunderstorms in Southern England, by Mr. G. M. Whipple.—Note on the appearance of St. Elmo's fire at Walton-on-the-Naze, September 3, 1889, by Mr W. H. Dines.—Notes on cirrus formation, by Mr. H. Helm Clayton. The author, who has made a special study of cloud forms and their changes, gives a number of notes and drawings on the formation of cirrus under various conditions, *e.g.* in a previously cloudless sky, cirrus bands with cross fibres, cirrus from cirro-cumulus clouds, cirrus drawn out from cumulus clouds, "mares-tail" cirrus, &c. Curved cirrus clouds when accompanied by decreasing barometric pressure frequently indicate that a storm of increasing energy is approaching.—A comparison between the Jordan and the Campbell-Stokes sunshine recorder, by Mr. F. C. Bayard. As a result of a year's comparison between these two instruments, the author found that the Jordan photographic recorder registered nearly 30 per cent. more sunshine than the Campbell burning recorder.—Sunshine, by Mr. A. B. MacDowall. This is a discussion of the hours of sunshine recorded at the stations of the Royal Meteorological Society.—On climatological observations at Ballyboley, co. Antrim, by Prof. S. A. Hill. This is the result of observations made during the five years 1884–88.

Geological Society, November 6.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—Contributions to our knowledge of the Dinosaurs of the Wealden and the Sauropterygians of the Purbeck and Oxford Clay, by R. Lydekker. The first section of this paper was devoted to the description of the remains of Iguanodonts from the Wadhurst Clay near Hastings collected by Mr. C. Dawson. They were considered to indicate two species, for which the names *Iguanodon hollingtoniensis* and *I. Fittoni* had been proposed in a preliminary notice. In the second section an imperfect metatarsus of a species of *Megalosaurus* from the Hastings Wealden was described, and shown to indicate a species quite distinct from the one to which a metatarsus from the Wealden of Cuckfield belonged. Two cervical vertebræ of a Sauropterygian from the Purbeck of the Isle of Portland were next described, and referred to *Cimoliosaurus portlandicus*, Owen, sp. The concluding section described an imperfect skeleton of a large Pliosaur from the Oxford Clay, in the collection of Mr. A. N. Leeds, which indicated a species intermediate between the typical Kimeridgian forms and the genus *Peloneustes*. These specimens were considered as probably referable to *Pliosaurus ferox*. Evidence was adduced to show that *Pliosaurus Evansi*, Seeley, should be transferred to *Peloneustes*. -Notes on a "dumb fault" or "wash-out" found in the Pleasley and Teversall Collieries, Derbyshire, by J. C. B. Hendy; communicated by the President.—On some Palæozoic Ostracoda from North America, Wales, and Ireland, by Prof. T. Rupert Jones, F.R.S. The specimens were described as nearly as possible in the order of their natural relationship, and thus, besides adding to the known forms, they were shown to illustrate the modifications exhibited by the genera and species of these minute bivalved Crustaceans, both in limited districts and in different regions. Amongst the forms described were the following new species and variety:—*Primitia mundula*, Jones, var. *cambrica*, nov.; *P. humilior*, sp. nov.; *P. Morgani*, sp. nov.; *P. Ulrichi*, sp. nov.; *P. Whitfieldi*, sp. nov.; *Entomis rhomboidea*, sp. nov.; *Strepula sigmoidalis*, sp. nov.; *Beyrichia Hallii*, sp. nov.; *Isochilina lineata*, sp. nov.; *I.? fabacea*, sp. nov.; *Leperditia Claypolei*, sp. nov.; *Xestoleberis Wrightii*, sp. nov.

Zoological Society, November 5.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a Report on the additions that had been made to the Society's Menagerie during the months of June, July, August, and September, 1889, and called attention to certain interesting accessions which had been received during that period. Amongst these were specially noted a Short Python (*Python curtus*), from Malacca, presented on July 2 by Mrs. Bertha M. L. Bonsor; and a Prêtre's Amazon (*Chrysotis prætrii*), purchased July 23: both new to the collection.—Mr. J. H. Gurney, Jun., exhibited and made remarks on a hybrid Wagtail, bred in confinement, between the Grey Wagtail (*Motacilla melanope*) and the Pied Wagtail (*M. lugubris*).—Mr. W. B. Tegetmeier exhibited and made remarks on some variations in the plumage of the Partridge (*Perdix cinerea*).—Prof. Bell exhibited and made remarks on two specimens of *Virgularia mirabilis*, recently dredged by the Hon. A. E. Gathorne Hardy, M.P., in Loch Craignish. He also exhibited two young living specimens of *Palinurus vulgaris*, received from Mr. Spencer, of Guernsey, in which the stridulating-organs were still capable of making sounds.—A communication was read from the Rev. Thomas R. R. Stebbing, containing an account of the Amphipodous Crustaceans of the genus *Urothoë*, and of a new allied genus proposed to be called *Urothoides*.—A communication was read from Colonel C. Swinhoe, containing descriptions of a large number of new Indian Lepidoptera, chiefly Heterocera.—Mr. P. L. Sclater gave an account of the birds collected by Mr. Ramage in St. Lucia, West Indies, which were referred to thirty species. —Mr. G. A. Boulenger read a note on the Short Python (*Python curtus*), a specimen of which was stated to be living in the Society's reptile house.—A communication was read from Dr. E. C. Stirling, of the University of Adelaide, on some points in the anatomy of the female organs of generation of the Kangaroo, especially in relation to the acts of impregnation and parturition. —Mr. F. E. Beddard read some notes on the anatomy of an Oligochætous Worm of the genus *Dero*, relating principally to its reproductive system.—A communication was read from Mr. Scott B. Wilson, in which were given the descriptions of four new species of Hawaiian birds, proposed to be called *Chrysomitridops cæruleirostris*, *Loxops flammea*, *Himatione montana*, and *H. stejnegeri*.

Mathematical Society, November 14.—Sir J. Cockle, F.R.S., Vice-President, in the chair.—The following gentlemen were elected to form the Council for the ensuing session:—President: J. J. Walker, F.R.S. Vice-Presidents: Sir J. Cockle, F.R.S., E. B. Elliott, and Prof. Greenhill, F.R.S. Treasurer: A. B. Kempe, F.R.S. Honorary Secretaries: M. Jenkins and R. Tucker. Other members: A. B. Basset, F.R.S., Prof. W. Burnside, Prof. Cayley, F.R.S., Dr. Glaisher, F.R.S., J. Hammond, Dr. Larmor, C. Leudesdorf, Major Macmahon, R.A., and S. Roberts, F.R.S.—The following papers were read:—Isoscelian hexagrams, by Mr. R. Tucker.—On Euler's ϕ-function, two notes by Mr. H. F. Baker and Major Macmahon (the former communicated by Mr. Jenkins).—On the extension and flexure of a thin elastic plane plate, by Mr. A. B. Basset, F.R.S.

PARIS.

Academy of Sciences, November 18.—M. Hermite in the chair.—On animal heat and the heats of formation and of combustion of urea, by MM. Berthelot and P. Petit. In connection with the production of animal heat the study of urea is of special interest, for next to carbon dioxide it is the chief form under which carbon is eliminated from the system, while almost all the nitrogen is eliminated as urea. Hence it is important to know how the production of urea in the organs is related to the heat of formation of urea, and of the substances from which it is derived. In the present paper the authors deal with the first problem, for the heat of combustion of urea in free oxygen has not yet been measured. Three concordant combustions in the calorimetric bomb yielded 151·8 C. per gram-molecule, and the molecular heat of solution of urea at about 11° C. is found to be − 3·58 C., whence the heat of formation of urea is 80·8 C., and of its solution in water or urine is found to be + 77·2 C.—On the orbit of Winnecke's periodical comet, by M. H. Faye. These remarks are made in connection with a memoir presented to the Academy by Baron von Haerdtl, on the movements of Winnecke's periodical comet. He arrives at the conclusion that there is no trace of acceleration in the mean movement. He finds that the mass of Jupiter must be raised to 1 : 1047·152, and determines that of Mercury in round numbers at 1 : 5,010,000 ± 700,000. This agrees pretty closely with the value 1 : 5,310,000 already obtained by Le Verrier.—Experimental study of the transits and occultations of Jupiter's satellites, by M. Ch. André. These observations have been made by means of an apparatus specially constructed by MM. Brunner, and here fully described. Particular attention was paid to the phenomenon of the luminous ligament which is formed near the point of contact. It begins to appear when the satellite is about 2½ minutes from real contact, gradually increasing in size and intensity as the two bodies draw near, so that at the instant of geometrical contact they appear to be connected by a veritable luminous bridge about one-third the breadth of the diameter of the satellite. The moment of geometrical contact is accompanied by optical appearances sufficiently distinct to serve as a base for the direct observation of the phenomenon.—Researches on the application of the measurement of rotatory power to the study of compounds resulting from the action of malic acid on sodium molybdate, by M. D. Gernez. In a previous communication (*Comptes rendus*, cix. p. 151) the author showed that solutions of malic acid, with molybdate of ammonia added, show sundry changes in rotatory power, which may easily be explained by assuming that definite compounds are formed between the substances. His present researches, made with the same acid and neutral sodium molybdate, lead to still more varied results, clearly showing the production of compounds between simple numbers of molecules of these bodies. The results, which are here tabulated and described, demonstrate that definite compounds are formed in solution on increasing the amount of one of the compounds regularly. They also show the defect of analytical methods claiming to deduce the composition of an active liquid from the measurement of its rotation, at least so far as regards substances analogous to those here under consideration.—On the ophthalmoscopic examination of the base of the eye in hypnotic subjects, by MM. Luys and Bacchi. Nine subjects (six women and three men) were examined, first in the normal state and then in various phases of catalepsy, lucid somnambulism, and hallucination. In some instances the iris was found to be excessively dilated and almost insensible to light. Other appearances are described, but no general inferences are drawn from these preliminary observations.—The second part of vol. i. of MM. Houzeau and Lancaster's "Bib-

liothèque générale de l'Astronomie," was presented by M. Faye, who remarked that this great compilation would not be interrupted by the death of M. Houzeau. The present volume comprises biographies, didactic and general works, spherical and theoretical astronomy, astronomical tables for all epochs, and treatises on calendars.

BERLIN.

Physical Society, October 25.—The President, Prof. Kundt, opened the meeting by a warm expression of regret at the loss sustained by the Society in the death of its late member, Dr. Robert von Helmholtz.—Prof. von Bezold spoke on the various causes which lead to the production of clouds and aqueous precipitates. Using the graphic methods which he had himself introduced into meteorology, he showed by means of diagrams that the older ideas on this subject are insufficient, and that, even in the case where both masses of air are saturated with aqueous vapour, the precipitation which may occur when they are mixed is not due to the mere mixing of warm and cold air: the temperature of the mixture is not the mean of that of the respective masses of air, but is somewhat higher, and the amount of water which is condensed on their mixing is very small. By means of his diagrams a simple solution is at once obtained of many problems which have reference to the temperature and humidity of masses of air when they are mixed together in unequal quantities. It appeared that under the most favourable conditions, when air saturated with aqueous vapour at 0° C. is mixed with air saturated at 20° C., under a pressure of 700 millimetres of mercury, only 0·6 grams of water is condensed out of 2 kilograms of the mixed portions of air. The same mass of water would be condensed out of the same mass of air saturated at 20° C. if its temperature were reduced to 19°·3 C., or if the air were to ascend through a height of 200 metres, in which case its temperature would fall to 18°·9 C. Much more massive aqueous precipitates are formed when moist air is either cooled directly, or has its pressure reduced by rising upwards, in which case a simultaneous cooling occurs. When air saturated at 2?° C. is cooled down to 10°·7 C.,—a temperature which results from mixing air at 24° C. with air at 0° C.,—4·4 grams of water are precipitated out of each kilogram of air, and if the temperature is reduced to 0° C., 8 grams are precipitated. Similar falls of temperature may be obtained during an adiabatic rise in altitude. The conditions which hold good for super-saturated air may similarly be comprehended by this graphic method. Notwithstanding that the formation of aqueous precipitates by the mere mixing of two masses of air is thus shown to be very minimal in amount, still it does occur in nature as the result of this cause, as, for instance, in the case of cloud-caps formed when different winds meet, and in the case of the formation of ground-fogs. According to the speaker, clouds ought to be distinguished by reference to the way in which the precipitate of which they consist is formed, rather than by the casual appearance which they present to the eye; in any case, mist and clouds must in the future be studied from the above new point of view.—Prof. von Helmholtz added to the above communication some remarks on the way in which the mixing of two fluids of different specific gravities is brought about. Such mixing is only possible as the result of vortex movements or of "breaking" waves. He had already dealt with the production of vortices, and the production of waves has recently engaged his attention, inasmuch as this problem has, up to the present, only been regarded from a one-sided point of view with reference to water, without taking into account the influence of the air which is moving over its surface. When wind blows over the surface of water, or when lighter air streams over a mass of heavier air, waves are formed, whose size and rate of propagation depend upon the relationship of the two fluids which are moving one over the other. To obtain the mechanical equations of these movements was the problem which he had set before himself for solution in a communication which he had recently made to the Berlin Academy. This dealt first with waves on water, and then the conditions involved in these were transferred to the consideration of waves in air. Waves 1 metre long on the surface of water, which are frequently met with in nature, correspond to waves in air 21 metres long—that is to say, to air-waves which extend over a considerable stretch of land. Waves in air are only visible in the cases where they are accompanied by condensations of vapour, the latter occurring in the case where the air rises several hundred metres to the crest of a wave. Prof. Helmholtz pointed out that the most important outcome of the whole theoretical consideration of the problem was the following: a quiescent surface of water over which a wind is blowing is in a state of unstable equilibrium; as the result of this, waves are produced as soon as the wind acquires a sufficient velocity, and the energy required to raise the water from the trough to the crest of each wave, as well as to produce the onward motion of the wave, is derived from the more rapidly-moving lower layers of air of which the wind consists. Friction plays a very subordinate part in the whole process.

November 8.—Prof. du Bois Reymond, President, in the chair.—Dr. Pernet demonstrated the latest and newest form of Edison's phonograph, and gave a minute description of the apparatus, illustrating his remarks by means of two instruments which were exhibited to the Society. He prefaced his description by a short historical introduction, from which it appeared that several years before Edison's discovery, a Frenchman named Gros had deposited with the Paris Academy a sealed packet containing a statement of the essentials for the construction of a phonograph.

Physiological Society, November 1.—Prof. du Bois Reymond, President, in the chair.—Dr. René du Bois Reymond spoke on the striated muscles which occur in the small intestine of the tench. The exceptional occurrence of striated muscles in the small intestine of this fish has long been known, as also that when the intestine is stimulated electrically it contracts suddenly, as does a skeletal muscle. The whole intestine is surrounded by these striated fibres arranged both longitudinally and circularly. Further examination revealed a very thin layer of both longitudinal and circular non-striated muscle-fibres, lying internally to the striated fibres. The only other known case of a similar occurrence of striated muscle-fibres in the walls of the small intestine is found in Cobitis; but in this fish the fibres do not extend as far as the rectum, as they do in the tench. The speaker set aside the idea that these striated muscle-fibres are connected with the respiratory function of the intestine, by showing that other fish are also in the habit of swallowing air, and that in such fish the mucous membrane of the small intestine is extremely rich in blood-vessels, whereas this is not the case in the tench. He put forward the suggestion that the striated fibres in the intestine of the tench are a transitional form between unstriated and striated muscle-fibres, and based his views upon the observation that, firstly, the reaction of these muscles is alkaline, and, secondly, upon an analysis of an aqueous extract of them. An aqueous extract of striated muscles contains, as is well known, three different proteids; one which coagulates at 47° C., one which comes down at 56° C., and a third coagulating at 70° C. The proteid which coagulates at 47° C. does not occur in unstriated muscles, and was similarly found to be absent in the extract of the striated muscles of the intestine of the tench. The function of these last-named muscles has not as yet been made out.—Prof. Fritsch spoke on the sensory organs in the skin of fishes. Starting from the simplest forms in which they occur as end-bulbs or tiny dilatations in the nerves which supply the several somites in the embryos of fishes, the speaker described their gradual change of form during growth. The end-organ is always characterized by sensory cells—that is to say, by cells which have a pear-like shape and are provided with a sensory filament or hair, and are connected with nerve-fibres. The developmental change which takes place is as follows: at first the organ becomes protected by being set deeper into the skin, spaces are then developed superficially to the organ, and these are finally placed in communication with the surface of the skin by means of a minute orifice or somewhat lengthy canal. The lateral-line organs of fishes in several modified forms is developed as above described; the sense-organ, with its sensory cells and nerves, lying at its base. A further modification leads to the development of the closed vesicles of Savi, which are completely filled with a mucous secretion. In the further modification of structure met with in the ampullæ of Lorenzini, a change of functional activity is already marked, as shown by the fact that the sensory cells have lost their hairs and have been converted into secretory cells. The speaker expressed his concurrence with that view of the function of dermal sense-organs, according to which they are to be regarded as auditory organs in a low stage of evolution, set aside for the perception of vibrations and waves which are propagated through the water.

Meteorological Society, November 5.—Dr. Vettin, President, in the chair.—The President spoke on the interchange of air which takes place between regions of high and regions of low pressure. He first described his own measurements of the altitudes of the various most characteristic forms of clouds, finding them in complete accord with those of Abercromby and Ekholm. He then passed on to his determinations of the velocity of the wind at those several altitudes, using as a means of measurement the records afforded by the direction and rate of motion of the clouds. The mean values thus obtained for the rate of flow of the air-currents were compared in each case with the positions of maximal and minimal air-pressure; from this comparison the speaker found that the motion of the air between points of maximum and minimum pressure does not take place in the way in which it has usually been supposed to occur. He then gave a detailed account of the results of his observations, but these do not admit of being reproduced within the limits of a brief abstract.

SYDNEY.

Royal Society of New South Wales, August 21.—A "reception" of the members of the Society was held for conversational scientific discussion, and the exhibition of various objects of interest: upwards of 100 members were present.

September 4.—Prof Liversidge, F.R.S., President, in the chair.—Mr. H. G. McKinney read a paper on irrigation in its relation to the pastoral industry in New South Wales, which was freely discussed.—Sir Alfred Roberts, Vice-President, exhibited a large collection of photo-micrographs taken by the late Captain Francis.

October 2.—Prof. Liversidge, F.R.S., President, in the chair.—The following papers were read:—The analysis of prickly pear; on the occurrence of arabin in the prickly pear (*Opuntia brasiliensis*), by W. M. Hamlet.—Personal recollections of the aboriginal tribes once inhabiting the Adelaide Plains of South Australia, by Edward Stephens.—The Chairman exhibited some interesting fungoid growths which had formed in water containing finely-divided gold in suspension. The gold had been precipitated from a weak solution of the chloride by phosphorus dissolved in ether; the mycelium of the fungoid growths had acquired a purple colour from the gold which it had absorbed; on incineration, a skeleton outline of the mycelium is left in gold.

AMSTERDAM.

Royal Academy of Sciences, October 26.—M. Mulder presented, for the Reports and Communications, an essay on tartarate of ethyl, and its relations to ethylate of sodium and potassium.—M. Grinwis spoke on two forms of energy occurring in rolling motion, and presented an essay on this subject for the Reports and Communications.—M. Rauwenhoff presented for the Transactions an essay in quarto, with plates, on the sexual generation of the Gleicheniaceæ, and communicated briefly the results to which his researches had led him.—M. van der Waals spoke of the equilibrium of solid compounds in presence of fluid and vapour mixtures, illustrated by the ψ surface of a mixture of two kinds of matter.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, NOVEMBER 28.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Electrical Engineering in America: G. L. Addenbrooke.

FRIDAY, NOVEMBER 29.

INSTITUTION OF CIVIL ENGINEERS, at 7.30.—Principles of Iron Foundry Practice: G. H. Sheffield.

SATURDAY, NOVEMBER 30.

ROYAL SOCIETY, at 4.—Anniversary.

ESSEX FIELD CLUB, at 7.—How to commence the Study of Botany: George Massee.

SUNDAY, DECEMBER 1.

SUNDAY LECTURE SOCIETY, at 4.—Invisible Stars; the Use of the Camera in the Observatory (with Oxyhydrogen Lantern Illustrations): Sir Robert S. Ball, F.R.S., Astronomer Royal, Ireland.

MONDAY, DECEMBER 2.

SOCIETY OF ARTS, at 8.—Modern Developments of Bread-making: William Jago.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Some Notes on Variations in the Products of the Destructive Distillation of Different Gas Coals, Heated Separately in the same Retort, and under Similar Conditions: Watson Smith.—Cresontinic Acid and its Applications: I. Hauff.

VICTORIA INSTITUTE, at 8.—Instinct and Reason: Dr. C. Collingwood.

ARISTOTELIAN SOCIETY, at 8.—The Æsthetic Theory of Ugliness: B. Bosanquet.

ROYAL INSTITUTION, at 5.—General Monthly Meeting.

TUESDAY, DECEMBER 3.

ZOOLOGICAL SOCIETY, at 8.30.—On the Anatomy of Burmeister's Cariama (Chunga burmeisteri).—On the Relations of the Fat-bodies of the Sauropsida: G. W. Butler.—List of the Reptiles, Batrachians, and Fresh-water Fishes, collected by Prof. Moesch in the District of Deli, Sumatra: G. A. Boulenger.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Ballot for the Election of Members.—Water-Tube Steam-Boilers for Marine Engines: John I. Thornycroft. (Discussion.)—The Triple-Expansion Engines at the Owens College, Manchester: Prof. Osborne Reynolds, F.R.S.

WEDNESDAY, DECEMBER 4.

THURSDAY, DECEMBER 5, 1889.

THE MANCHESTER CONFERENCE.

THE Manchester Conference on the working of the Technical Instruction Act was as important a representative gathering as has taken place for some years to consider an educational question. The Conference was called by the Technical Association, and the Executive Committee and the branch Associations throughout the country were strongly represented. Invitations were also addressed to the chief local authorities and School Boards in large centres, and the principal technical schools and institutions. It says much for the change which has come over public opinion in the last two years on educational matters, that a circular, unadorned by promises of party speeches by prominent M.P.'s, but merely inviting discussion on the details of the operation of an Education Act, should have sufficed to cram the Mayor's parlour with a body of nearly 300 delegates, representing more than sixty local authorities and institutions.

"Conferences," Mr. Acland said at the outset, "are usually disappointing," and it would be absurd to expect that so large and miscellaneous a gathering would dispose satisfactorily, within little more than a couple of hours, of the four difficult questions raised on the agenda sheet. But such progress as was possible was made, and the remorseless bell sounded with impartiality when a speaker's limit of five minutes had been reached. In this way a good many expressions of opinion from many different points of view were compressed into the afternoon, and few could have gone away without any new ideas suggested by the Conference. That is, if they had previously taken the trouble to acquaint themselves with the provisions of the Act, for no time was wasted in the room in explaining its general scope, though literature in abundance on the subject could be had from the bookstall at the door.

The subjects discussed were: the relation of the Act to elementary schools; the mode of its adoption and the preliminary proceedings connected therewith; the mode in which, and the conditions under which, grants may best be made by local authorities to institutions giving technical instruction, and the principle on which such grants should be apportioned among institutions of different grades; and the mode of re-organization by which the Science and Art Department may meet the new duties imposed upon it by the Act. The four speakers who introduced these subjects happily represented the four chief "interests" involved—education, politics, manufactures, and science.

Without following in detail the order of the discussion, we may briefly sum up the impression which it left.

The chief interest centred in the question of the relation of the Act to public elementary schools. It is no secret that a certain amount of misunderstanding and difficulty has arisen over the interpretation of the sections of the Act which bear on this knotty point. The Act forbids the application of rates raised under it to the instruction of scholars working in the "obligatory or standard subjects" of the Code. The meaning so far is clear. No scholar of an elementary school at the time working in any of the standards can take advantage of the Act. But how about ex-seventh standard scholars, or indeed of any children in elementary schools, above the exemption standard, to whom the managers may wish to give technical instruction? It is well known that, in many Board and some voluntary schools, a large number of children are retained who have passed all the standards, but are receiving science and art instruction, and earning grants from South Kensington. What are the powers of Boards and managers with respect to these children? One thing is certain—whatever Boards could do before the Act, that at least they can do still. There is no restrictive clause in the Act, which purposely enacts that "nothing in this Act shall be so construed as to interfere with any existing powers of School Boards with respect to the provision of technical and manual instruction." But there has always been some little doubt as to the exact status of School Boards with respect to higher elementary schools, and this the Act does nothing to remove. Sir Henry Roscoe's Bill, if carried, would have placed the whole position of higher elementary instruction on a sound and satisfactory basis. It is a great flaw in the present Act that it leaves matters where they were. It is, however, an ill wind that blows nobody any good, and it may be that certain advantages will, after all, result from this anomalous state of things. Opinions of experts not being unanimous about the meaning of the Act, it is clearly a time for experiments to be made. Liverpool is already moving in the matter, after obtaining Sir Horace Davey's opinion that it is within the power of the School Board to provide technical and manual instruction out of the rates under their general powers, and other School Boards need have little fear in taking a comprehensive view of the Act and applying to the City Councils for their share of the proceeds of the special rate.

The Conference also discussed the question whether a local authority is bound to distribute any grant which it may make among the different qualified schools which apply for aid, or whether it may take the initiative and adopt the course (in many cases the wisest) of concentrating its efforts on making one central school efficient. This question, on which some doubt was previously felt owing to the obscurity of the wording of the Act, was satisfactorily cleared up at Manchester. The town clerk of Blackburn threw down the challenge, by declaring that he intended to advise his Council that they had the power to build a technical school and give it all, or the greater part, of the proceeds of the rate. To this General Donnelly replied that there was nothing in this to which he could take exception, so that local authorities have—so far as the Science and Art Department is concerned—greater liberty of action than some had supposed; and who can object except the Science and Art Department?

But, perhaps, a question of more real importance even than this, is the nature of the qualification entitling a technical school to rate-aid. Here, again, the wording of the Act is not very clear, and it must be confessed that the discussion at the Conference still left it in doubt. In Section I., Sub-section (*a*), we read: "A Local Authority may, on the request of a School Board for its district or

any part of its district, or of any other managers of a school or institution within its district *for the time being in receipt of aid from the Department of Science and Art*," make provision for technical education in its district. The narrowest interpretation of this clause would confine the whole benefit of the Act to schools already receiving grants from South Kensington, and this view was understood by some members of the Conference—we hope wrongly—to be endorsed by General Donnelly.

We need hardly point out that such an interpretation would seriously restrict and cripple the operation of the Act. If there is one conclusion clearer than another from the Manchester Conference, it is that there is a general wish to use the rate for what we may venture to term its legitimate purpose—the assistance of those technical subjects which are not at present included in the Science and Art Directory. The worst thing that could be done would be to fritter it away in the form of doles to existing science and art classes; and yet, if only grant-earning schools can profit by the Act, this is what will inevitably tend to take place. Such an institution as the Leicester Technical School, which has classes in bootmaking, lace-making, &c., but no science and art classes, could get no help. The same would be true of such a school as the Finsbury Technical College.

We are glad to believe that so narrowing a meaning cannot fairly be given to the wording of the section. It is true that the words we have italicised make it necessary that the first institution to make a request to the local authority to put the Act in force must be already in connection with South Kensington, if it is not a School Board. But this condition only applies to the initial proceedings. When the request is made and granted, the local authority may make, "to such an extent as may be reasonably sufficient having regard to the requirements of the district, but subject to the conditions and restrictions contained in this section, provision in aid of the technical and manual instruction for the time being supplied" (not only in the school which makes the request, but) "*in schools or institutions within its district.*"

That is, it may aid all higher schools already giving instruction which falls within the four corners of the Act, and this instruction includes very much more than the list of subjects on which grants can at present be earned.

And this leads us to the further question, What is meant by technical instruction in the Act? Some people, even at the Conference, understood it to mean merely the subjects in the Science and Art Directory, and any others which may be sanctioned by the Department on the representation of a local authority. This interpretation, again, would severely cripple the usefulness of the Act. At a time when the public is beginning to realize the mechanical nature of much of the teaching subsidized by South Kensington, and the want of elasticity and local adaptability which inevitably results from over-centralization, it would be nothing less than a disaster to tie down all science and art, and perhaps even technological teaching, to the rigid syllabus of a Government Department. Chemistry *quâ* chemistry would not be a "technical" subject, unless, forsooth, it were taught according to a certain syllabus, and followed by a certain examination. No really "technical" subject (except the four or five which are included in the Directory) would be "technical" under the Act until the local authorities in each district (not, be it noted, the managers of schools) had made a representation on the subject to the Science and Art Department, and a minute had been laid before Parliament.

But here, again, we are strongly of opinion that no such meaning can fairly be attached to the definition. "Technical instruction," so runs Clause 8, "shall mean instruction in *the principles of science and art applicable to industries, and in the application of special branches of science and art to specific industries and employments. It shall not include teaching the practice of any trade or industry or employment.*" There is the definition. What follows is not a restriction, but an amplification, intended to provide a mode of clearing up doubtful cases. Some one might hereafter declare that some subject, as, for example, mathematics or landscape-painting, though included in the Directory, was not contemplated by the Act, as not being "instruction in the principles of science and art applicable to industries." The section therefore expressly declares that the definition *shall* include all such subjects; and if there be any other subject outside the Directory about which doubt is entertained, that doubt may be set at rest by a representation from a local authority. The Science and Art Department is umpire in doubtful cases, but no appeal to the Department is necessary with reference to subjects—say the principles of weaving, dyeing, plumbing, &c.,—which fall unmistakably within the definition. That, at least, is our view, and we believe the only rational one. It seems to us as clearly the meaning of the letter of the Act, as it was certainly the intention of its promoters.

The Science and Art Department, however, will have the power to define the mode of teaching of technical subjects for the purpose of earning Imperial, though not local, grants. The Department might, as was suggested at Manchester by Principal Garnett, take over the whole system of grants and examinations now controlled by the City and Guilds Institute. But we venture to hope—and Principal Garnett himself would, we believe, agree in this—that the authorities at South Kensington will think very carefully before embarking on a new system of payments on results, in the case of subjects which admit far less of such a test than most of those included in the Science and Art Directory.

They would do well to rely far more on efficient inspection than on individual examinations, and if the inspection were made a reality, instead of being, as now, too often a farce, they might, perhaps, ultimately base their grants for technical instruction on the amount of local contributions, in some such way as that provided for in the Welsh Intermediate Education Act. The Manchester Conference was strongly opposed to any increase of centralization, and the greatest possible freedom ought to be allowed to localities from the outset to develop their own system to suit their own needs.

If the Conference was decided on this point, it was, we think, equally decided that, under a broad interpretation of the Act, the powers conferred on local authorities are really very extensive. It is little short of a scandal that an Act for the improvement of English industry should itself offer such an exhibition of bad workmanship. But

it is clear that the right way to solve the problem is for local authorities and School Boards to push ahead, as we believe they can do without fear. The list read by Sir Henry Roscoe at the opening of the proceedings shows what progress in this direction has already been made towards adopting the Act, and the Conference can hardly fail to result in a still more vigorous attempt to make a wise and extensive use of its provisions.

AMERICAN ETHNOLOGICAL REPORTS.

Sixth Annual Report of the Bureau of Ethnology to the Secretary of the Smithsonian Institution, 1884–85. By J. W. Powell, Director. (Washington: Government Printing Office, 1888.)

FROM the introductory remarks of the Director of the Bureau, we learn that the results of the research prosecuted among the North American Indians, as directed by Act of Congress, were of special interest during the continuance of the work in the fiscal year 1884–85.

As in forme years, the labourers in the mound explorations were remarkably successful, more especially in the territories east of the Rocky Mountains, where Prof. Cyrus Thomas, in 1885, and his coadjutors, Messrs. Middleton and Thing, subsequently, made important finds in Indian pottery, which were unique of their kind. Even more valuable are the results of the explorations carried on in New Mexico by Mr. and Mrs. Stevenson, the latter of whom succeeded in obtaining the largest and most important collection extant of objects relating to the sociology of the Zuni tribes. This rare treasury of Indian relics includes specimens of woven fabrics, pottery, stone implements, both ancient and modern, pictured urns, shrines, altars, sacred masks, fetishes, plume sticks, and other objects connected with the ancient mythology and religious practices of these people. Owing to the great variety of the objects, their true character cannot be determined without prolonged investigation, and in the meanwhile they have been deposited in the U.S. Museum, where they await their final classification. According, however, to Mr. Curtis, these, as well as the still more numerous collections of pottery, stone implements, and other objects, amounting to 4000 specimens, which have been obtained in New Mexico, all belong to the indigenous arts and industries of the ancient tribes who occupied the almost unknown tracts of Central America in which the Pueblo Indians are now located.

In the department of linguistic research, prosecuted by the various *employés* of the Bureau, none have perhaps been more successful than Mrs. Ermine Smith, who was fortunate enough to discover two Onondaga MSS., and one MS. in the Mohawk dialect, all of which she has annotated and translated with the assistance of a half-caste of Tuscaroran descent. The origin and history of these MSS. are not distinctly known, but it is conjectured that they are copies of originals which have been lost or destroyed. In their present form, they are, however, alike interesting from a sociological and a linguistic point of view, for while the Mohawk MS. gives an account of the religious rites and chants of the Iroquoian League, which represented the elder members of the entire nation, one of the Onondaga MSS. records the ritual in use among the younger members of the same council, and the other the form of address used by the chief Shaman on the initiation of a newly elected chief.

These curious records have been turned to good account by Mrs. Smith in the completion of her Tuscarora dictionary, and in filling up her vocabulary for the "Introduction to the Study of the Indian Languages" now preparing for publication.

In the Far West, and especially in California, the results of linguistic field-work are not equally satisfactory; and in the latter province, it would appear from the report of Mr. Henshaw, who was charged with the inquiry, that a number of the native dialects are extinct. Only a month before his arrival, an old woman had died who was the last person to speak the language of the Indians of Santa Cruz. The search for still surviving members of the several families of Indian languages current on the arrival of the Spaniards has not, therefore, begun too soon. The general results of these linguistic researches are embodied in a work entitled "Proof-Sheets of a Bibliography of the Languages of the North American Indians." This volume, a quarto of more than 1100 pages, was compiled by Mr. Pilling, and issued in 1884 by the Institute, which, with its usual liberality, has distributed the hundred copies printed to other public institutions, and to the various collaborators in the work.

In turning from the highly interesting explanatory remarks of the Director to the various monographs contained in the volume before us (a folio of more than 800 pages), we have first to notice the comprehensive and profusely illustrated treatise of Mr. Holmes, "On the Ancient Art of Chiriqui on the Isthmus of Panama."

Here the author supplies the technologist with an exhaustive history of the rise and development of plastic and textile art in this part of the continent, while he also treats fully of the literature and geography of this hitherto little-known province, whose position between North and South America imparted to the people some of the characteristics of the civilization of both sections of the western hemisphere.

Almost the whole of the enormous mass of clay and metal objects found in Chiriqui was extracted from tombs in the various *huancals*, or cemeteries, which are scattered over the Pacific slope of the province. These were first made known to science by Mr. Merritt, the director of a gold mine in Veragua, who, on hearing of the accidental discovery of a gold figure in Chiriqui, visited the district, and published a report of his explorations in 1859. From him we learn that in 1858, after it became known that a golden image had been discovered at Bugava, more than 1000 persons flocked to the spot, who it was estimated had in that year collected 50,000 dollars' worth of gold from one cemetery alone, which had an area of only 12 acres. A curious fact connected with the plastic decorations of the Chiriqui vases and other objects is that no vegetable forms have served the artificers as models, animals alone having been used for the purpose, as crocodiles, armadillos, monkeys, lizards, alligators, owing probably to their zoo-mythic conceptions of their divinities. Among the various groups of vases, the one comprising the so-called "alligator ware" is the most interest-

ing; this animal being not only represented as a surface ornament, but serving as a model for the form of such dissimilar objects as whistles, rattles, tables, stools, jars, vases and other utensils. Occasionally the human figure appears under some grotesque form, and less frequently it is used to represent a divinity. According to Mr. Holmes, the entire system of the scrolls, frets, and other devices used in Chiriqui art have been derived from various parts of the body of an animal, probably the alligator, and he regards this system of ornamentation as indigenous to the district. In a separate article, the author treats of textile art in its relations to the development of form and ornament, and more especially with respect to the industries of the early American people.

The article on the Central Eskimo, by Dr. Franz Boas, although complete and admirable of its kind, has comparatively little interest for the English reader conversant with the results of Arctic research, since a very large and important part of the information given has been derived from the narratives of Franklin, Ross, Parry, and other more recent British explorers. Yet some additions have been made to our older knowledge of the Eskimo by Dr. Boas, who gives much interesting information regarding their tribal laws and customs, the musical art of the people, and their capacity for drawing; while he relates several curious tales and traditions, which present so remarkable a similarity to those of the Greenlanders and the Behring Straits' tribes as to make it probable that all these people are of one race.

The Rev. O. N. Dorsey, to whom the Bureau is indebted for the compilation of seventeen vocabularies of the different dialects used by the Oregon Indians, adds an interesting contribution to this volume, in which he describes the results of his visit, in 1883, to the Osages in the Indian Territory. During his short stay he obtained information regarding the existence of a secret society of seven degrees, in which a knowledge is preserved of the grades and general history of the various gentes and subgentes, with their taboo and names which are regarded with reverence and not spoken of. Owing to the strict secrecy usually maintained by members of this society, it was with extreme difficulty that he induced two of the initiated to recite to him the traditions referring to the mythic history of their tribe, which had been imparted to them on their initiation. These traditions, which the author gives with an interlinear translation, record the passage of the primæval Osages from higher worlds before they bore the semblance of birds, or had acquired from a beneficent red eagle the bodies and souls with which they alighted on the earth. The sacred chart on which their descent was symbolized by a river flowing beside a cedar, the tree of life, surrounded by sun, moon, and stars, was observed by Mr. Dorsey to be tattooed on the throats and chests of some of the elder men; but the younger Osages knew nothing of such symbols, and he was asked not to speak to them on the subject. From all he saw and heard among these and various tribes of Iowa and Kansas, he believes that in this traditional record of the descent of their gentes from different birds and animals, we have a clue not only to the names by which they are distinguished, but to the meaning of the chants and war-songs which only members of the seven degrees of their sacred societies have the right to sing. It would appear that an arrangement by sevens is common to various kindred tribes, and there is reason for assuming that wherever mythic names or taboos are in use there are, or have been, secret societies or mysteries, which have been derived from early traditional history.

In an elaborate article by Prof. Cyrus Thomas, entitled "Aids to the Study of the Maya Codices," we have an interesting account of the far-famed Maya Codex, which was acquired by the Royal Library of Dresden in 1739, and a large portion of which was collated for Lord Kingsborough's great work on "Mexican Antiquities," of which it forms the larger part of the third volume. According to Dr. Thomas, this unique document consists not merely of one, but of several original MSS., while it presents no evidence, as often asserted, that its symbols, figures, and signs are to be accepted as alphabetical, or phonetic, characters, its series of dots and lines seeming to indicate a close relationship with the pictographic system in use amongst the North American Indians. He is of opinion that these series have a chronological significance, based on the method of counting time common to the Mexicans and Mayas, in which a religious, or hierarchical, cycle of 260 days was recognized, as well as the solar year calendar of 360 days in use among the people. This interpretation must, however, for the present rank as merely conjectural, although his elaborate analyses of the Maya symbols cannot fail to be of use to the few interested in the solution of the curious philological problem involved in the elucidation of this unique codex, to which special notice was first drawn by Alexander von Humboldt. His acquaintance with ancient South American MSS. enabled him to show that, while its symbolic characters presented a close affinity with those used by the Mexicans, the material of which the MS. was composed was the Mexican plant metl, *Agave mexicana*.

EXACT THERMOMETRY.

Traité pratique de la Thermométrie de précision. Par Ch. Ed. Guillaume. Pp. xv. and 336. (Paris: Gauthier-Villars, 1889.)

THE thermometer, practically as we now have it, is an instrument several centuries old, and by far the most popular of all scientific apparatus. Yet probably much less is generally known about it than about its companion implements the barometer and the telescope. The reason for this want of knowledge lies doubtless in the fact that the common use of the thermometer is chiefly for rough observations on the temperature of the air, and for this the ordinary instruments are sufficiently accurate as they leave the maker.

Meteorologists and physicians, however, occasionally have the zeros of their thermometers tested; and, for factory work, other points have sometimes to be examined. But in chemical and physical laboratories, investigations not unfrequently require that thermometers should be corrected with all possible delicacy, if the resulting measurement is to be exact and valuable. For such operations there has hitherto been no exhaustive guide; and M. Guillaume, whose ample experience in the Bureau international des Poids et Mesures is a guarantee for the practical value of what he writes, has done good service by issuing the present work at an opportune moment.

It is natural for a "Traité pratique" to refer mainly to the mercurial thermometer; for the great majority of practical thermometric measurements lie within its scope. Having a range from -40° to at least 360° C., and a possible sensitiveness of about $0^\circ{\cdot}001$, it rarely has to be exchanged for more delicate or larger-scaled appliances. Even the air thermometer—a sort of general appeal court in measurements of heat—is always accompanied by a number of ancillary mercurial thermometers.

To begin at the beginning (which, by the way, the author has not done), a thermometer has to be made; and the method of making it has a serious influence on the result. One maker will overheat his glass, and thus make the bulb harder than the stem; another will leave irregularities in the bulb which will cause the zero to rise irregularly; a third can never perfectly "deprive," as it is termed, the stem of air; the breath of a fourth is constantly leaving fatty matter in the capillary tube. In short, there are endless variations in technique, to which, for delicate instruments, attention should be drawn.

The division of the thermometer is, as might have been expected, well described; and minute details of calibration (chiefly by the method of broken threads) are duly set forth. Then follows a notice of a less familiar correction—that, namely, which depends on internal pressure when the thermometer is in a vertical position, and that which is produced by the (external) pressure of the air. Two methods of ascertaining the thickness of the bulb are given, but they are both inferior to Stokes's, which turns upon measuring angularly the distance between a spot on the outside of the glass and its reflection from the inner surface. Then ensues a description of the usual apparatus for determining the zero (which M. Guillaume seems to read somewhat too soon after immersing the bulb in the bath); and the method of ascertaining the boiling-point of water accompanies this. In the comparison of thermometers, which is next treated, the present writer prefers an air current to the metal plunger figured on p. 125.

If we observe the zero of a thermometer soon after manufacture, and subsequently at frequent intervals, we shall find that it is continually rising. The late Dr. Joule observed this ascent in one of his thermometers for more than seven-and-twenty years. There can be no doubt that it is due to a kind of setting of harder silicates in presence of softer or more viscous silicates in the mixture of which the bulb is composed. The softer glasses show it more than the harder ones; but in all exact work, it has to be determined and allowed for. This variation takes place at the ordinary temperature. If now we heat the thermometer moderately (say to 100°) and cool it, we shall notice a temporary depression due to a temporary set. If, again, as is often the case in factory work, we heat the thermometer for a long time to a high temperature (say 180°) the glass of the bulb (especially if soft) will become sensibly more plastic; and will sometimes yield sufficiently to external pressure to cause an ascent of 6°. At higher temperatures the ascent is still greater. Measurements of zero are therefore exceedingly important, even for moderately accurate work, and the author does not fail to draw minute attention to them. We should have been glad if at this point he had said something about the form of thermometer bulbs. Bulbs, for instance, which have their sides concave vary readily in capacity with barometric changes.

The exposure correction has exercised the minds of physicists for a great many years. When the bulb but not the stem of a thermometer is in a bath, the stem may clearly have a different temperature from the bulb, and the reading as a whole will be too low. In most chemical and physical laboratories, it is usual to follow Regnault, and to add, to the otherwise corrected reading T., the quantity

$$\alpha(T - t)N.$$

(N is the length in degrees of the exposed column, t is its mean temperature, and α is the difference between the expansion coefficients of glass and mercury.) There can be no doubt that this correction gives too low a result at high temperatures. It has been shown that if instead of α we simply write $(\alpha + \beta N)$—calculating α and β from the results—the demands of experiment are fulfilled with all desirable accuracy. The author, however, is disposed to leave the reader pretty much to his own devices for this correction.

The remainder of M. Guillaume's work is chiefly devoted to the comparison of the mercurial with the gas thermometer, and the measurement of dilatation of solid bodies: there are some valuable tables at the end.

A perusal of this "Traité pratique" will perhaps cause some regret that in most of our measurements of temperature we should be obliged to employ a material that is constantly undergoing physical change, and that necessitates in instruments constructed of it so many corrections. It is, on the other hand, a fortunate circumstance that we have in the mercurial thermometer an admirable means of establishing and measuring the corrections necessary to be imposed wherever glass is accurately worked with. For it cannot be too emphatically pointed out that every lens, cylinder, flask, or other glass instrument we employ is more or less amenable to these corrections. M. Guillaume's work, therefore, should command, as it deserves to command, a very wide interest. EDMUND J. MILLS.

THE FAUNA OF BRITISH INDIA.

The Fauna of British India, including Ceylon and Burma. Edited by W. T. Blanford. Vol. I. Fishes. By Francis Day. Pp. 548; 164 Figs. (London: Taylor and Francis, 1889.)

THE first volume of this, the last work of the well-known Indian ichthyologist, Francis Day, was issued under particularly painful circumstances, viz. almost on the very day of the author's death. The state of Mr. Day's health during the last few months had prevented him from attending to the correction of the proofs beyond the middle of this volume, which deals with the Chondropterygians, the Physostomes, and the Acanthopterygian family *Percidæ;* and the task of carrying the remainder through the press has fallen on the editor. This work is but a condensation of the author's quarto "Fishes of India," completed in 1878, so valuable for the copious and beautifully-executed lithographic plates which accompany it. And, fortunately, a number of these excellent illustrations (one for every

genus) have been reproduced, intercalated in the text, in a manner which is highly creditable to the Lithographic Etching Company.

Considering how much remains to be done in the investigation of the fish-fauna of India and its British dependencies, it is a matter of regret that so little attention has been paid to the subject since Mr. Day's departure from India. The supplement to the "Fishes of India," published in 1888, records no more than sixty additions to the number of species, a figure which might easily have been doubled in the same lapse of ten years but for the unaccountable want of interest shown in this most important branch of study. As an example of the results which may be attained by an enthusiastic collector in those regions, we may allude to the collections of fishes brought together during the last three or four years by Mr. Jayakar, a surgeon stationed at Muscat, at the entrance of the Persian Gulf, and presented by him to the British Museum, by which no less than twenty-five species, many of large size and of commercial importance, have been added to the record of the fishes of the Indian Ocean. It is to be hoped, therefore, that this new and well got up issue of the "Fishes of India" in a more portable form will give a fresh stimulus to the study of that fauna. A little more, however, might have been done to facilitate the identification of species, a particularly arduous task, the difficulties of which would have been greatly lessened by the preparation of satisfactory "keys." Such as they appear in this work, viz. mere abbreviated tabulations of characters, without or with scarcely any groupings under special headings, the synopses fail in their object, and it is really a matter of regret that the editor did not bring his influence to bear for a thorough recasting of this portion of the work, especially in the case of such extensive genera as *Barbus*, *Nemachilus*, *Lutjanus*, or *Serranus*, where the work of identifying species by means of the synopsis given is perfectly discouraging. With the enormous multitude of species which our present knowledge requires us to grasp, it is of primary importance that every possible facility should be given to the naturalist who uses a manual of this kind, which after all is intended chiefly for those who have but an elementary knowledge of the special subject.

The above notice was in type when we received a copy of the second and concluding volume (509 pp., 177 figs.). We are glad to see that the editor has, in many cases, recast the synopsis of genera and species. The total number of fishes known from Indian waters is given as 1418.

In concluding, we congratulate Mr. Blanford on having, under difficult circumstances, so successfully brought out this portion of the "Fauna of India"; and we join in his tribute to the memory of the late author, who, as he justly says, has rendered signal service to Indian zoology.

OUR BOOK SHELF.

La France Préhistorique. Par Émile Cartailhac. (Paris: Félix Alcan, 1889.)

THIS volume forms one of the well-known series, "Bibliothèque Scientifique Internationale," published under the direction of M. Ém. Alglave. The subject, we need scarcely say, is one with which M. Cartailhac is eminently competent to deal, and all who are interested in the study of prehistoric times will be glad to have so compact and lucid an account of the facts to which the work relates. He begins with a good sketch of the rise and progress of modern ideas with regard to primitive civilizations and the antiquity of the human race; and this is followed by a discussion of the questions connected with man's place in Nature, his origin, and the supposed traces of his existence during the Tertiary period. An admirable chapter is devoted to the striking manifestations of artistic impulse by men of the Palæolithic age. The monuments of the Neolithic era in France are grouped with perfect clearness, and M. Cartailhac has not failed to do justice to any one of the various questions which these monuments have forced upon the attention of students. The scientific value of the book is enhanced by the fact that he avoids as much as possible the use of purely hypothetical reasoning. When he comes to sets of phenomena which cannot be simply and naturally accounted for, he thinks it better to offer no theory at all than to suggest purely conjectural explanations. The illustrations, although in no way remarkable, will be of considerable service to readers who have not made themselves familiar with the aims and methods of archæological science.

Experimental Science (Elementary, Practical, and Experimental Physics). By George M. Hopkins. (New York: Munn and Co. London: E. and F. N. Spon, 1890.)

THE subject of experimental physics is here set forth in a manner calculated to afford to the student, the artisan, and the mechanic, a ready and enjoyable method of acquiring a knowledge of this fascinating subject. Although the popular style adopted by the author perhaps makes the book better suited to the general reader than to the student, it may safely be said that all classes of readers will find much to interest them. All the subjects usually included in the comprehensive term "physics" are discussed; and, in addition, photography, microscopy, and lantern manipulation. By carefully performing each experiment at the time of writing the description, the author guarantees certain success if his instructions are followed. There is an excellent chapter on "mechanical operations," containing many valuable hints on glass working, simple apparatus for laboratory use, soldering, and moulding. Mathematical expressions are almost entirely excluded.

The book is chiefly remarkable for its hundreds of excellent illustrations, very few of which are diagrammatic. Many of them, like a considerable portion of the text, have already appeared in the *Scientific American*, which is alone sufficient guarantee of their quality. Some of the latest inventions, including Edison's new phonograph, are described and illustrated.

"Modern Views of Electricity."

THE only point really at issue between Prof. Lodge and myself seems to be whether the difference of potential between two metals in contact can be measured by the Peltier effect or not. He asserts that he regards the statement that it can as an axiom, while I maintain that the only reason for calling it an axiom is that it cannot be proved. Let us take a simple case. Suppose we have a condenser, the plates of which are made of two different metals metallically connected, and that this con-

denser is placed in a vacuum, then, so far as I can see, Prof. Lodge's principle must lead to the conclusion that the difference of potential between the plates of the condenser is proportional to the Peltier effect; but if this is so, it is quite easy to show by the second law of thermodynamics that if the system is regarded as a heat-engine, the Peltier effect cannot vanish except at the zero of absolute temperature.

On the other points mentioned by Prof. Lodge in his letter, there does not seem sufficient difference of opinion between us to make it worth while discussing them.

In conclusion, let me assure Prof. Lodge that I am thoroughly in sympathy with the view that the consideration of the behaviour of the medium in the electric field is absolutely essential. I do not think there is anything inconsistent with this in the paragraph he quotes, which was intended to express what is well known to have been the opinion of Maxwell himself—that the key to the secret of electricity would be found in the "vacuum" tube.

THE REVIEWER.

The Physics of the Sub-oceanic Crust.

IN your article on the above subject in NATURE of November 21 (p. 54), the important proposition that the earth's crust rests on a liquid layer is once more brought to the front. The question reaches to the very basis of geology, but, like most of those of real importance, is not now recognized by the Society which occupies apartments in Burlington House, rent free, for the purpose of forwarding the study of geology.

Nothing is more obvious to the geological student than that enormous thicknesses of strata have been formed at practically one level. We do not find that, when a thousand feet of sediment has been deposited under water, the deposition began in water which was 1000 feet deep, and went on gradually lessening the depth until the sea or lake was filled up; but we do find, as in the coal-measures, that the entire 1000 feet was deposited in most uniformly shallow water; that therefore the crust of the earth must have sagged foot by foot as additional feet of burdens were laid upon it. Deltas that have not yet been bottomed show hundreds of feet of silt, every yard of which was deposited at only a few feet from the surface level of the water; estuaries and river valleys slowly sink where there is sedimentation; ice-caps tell of accumulation accompanied by depression and submergence, and re-elevation when the burden is melted and dissipated; coral formations and submergence are regarded as well-nigh inseparable, and even lava-flows flowing on to a plain have sunk its level in a degree corresponding with their mass. Where there is fifty or a thousand feet of piled-up lava-sheets you may look for a fault of like amount on its flanks, like that which, still unsuspected by geologists, cuts the Isle of Mull in half. Whether we look at the past or the present, we seem to see evidence of a crust resting in equilibrium on a liquid layer, and sensitive to even apparently insignificant readjustments of its weight. And if the crust did not respond to, and make room for, the burdens laid upon it by the removal of disintegrated land and its redeposition as silt under water, would not the seas be choked for miles round every coast? The abrading action of the waves cuts down the land, be it high or low, to a dead uniform level, and sooner or later it must become first beach, and then sea-bottom. There it is covered with silt or sea-weed, and is no longer abraded, and would, therefore, form great level tracts, instead of almost uniformly shelving coasts, unless it yielded *pari passu* to the increasing weight of sediment and water. The immediate effect of cutting down cliffs, say of 100 feet in height, and removing them in solution or by wave action, is to relieve the pressure at their base; and I claim that, wherever I have excavated for the purposes of collecting under such conditions, I have found a decided slope inwards away from the sea, if the strata were at all horizontal, no matter what direction their general inclination might be at a distance from the sea margin. But on the beach, a little way from the base of the cliffs, the slope is, on the contrary, towards the sea, and whatever the general inclination may be, we see the harder ledges, even if but a few inches thick, sloping away into deeper and deeper water until lost to view; and if you choose to follow them and dredge, you trace them tending downwards into yet deeper water. This appears to me to be simply because the relief from pressure has made the beach-line the crown of a slight arch, and an arch that continues to grow and travel, else how could we collect day after day and year after year, on the same spots, such as Eastware or Bracklesham Bays, fresh crops of fossils after every tide? I have hundreds of times picked up every vestige of a fossil on perhaps an acre of Eocene or Gault, yet a couple of tides have removed so appreciable a layer that the area has appeared studded with fresh specimens that were twenty-four hours previously wholly covered and concealed under matrix. Yet this ceaseless waste does not lower the level of the beach as it ought to.

And if such slight displacements as result from coast denudation have so appreciable an effect, what must take place in ocean, if subsidence is going on, and the weight of water on the increase? Darwin saw that the vast rise of land, which he so graphically describes in South America, must have been accompanied by a corresponding depression in the bordering oceans; and in turning his pages you almost expect to come on the view that depression in the Pacific must be the cause of the upheaval of the coast-line. It only wanted the liquid layer theory to make the dependence of one on the other obvious. No general rise of land has, or ever can, take place, under the overwhelming pressure of the great ocean depths, and oceans are thus permanent; the struggle is confined to whether the liquid layer shall overcome lateral resistance and find relief along the coast-lines, which are the nearest lines of least resistance, and already weakened by abrasion, forming coast ranges, or rending the crust, and pouring over thousands of square miles from fissure eruptions; or whether it shall overcome vertical resistance, and raise the beds of shallower ocean eventually, perhaps, into land.

Thus the tendency, as noticed by the writer of your article, is for deep oceans to become deeper, under pressure which may increase but never relaxes, and for mountain-chains to grow into higher peaks, the more weight is lessened by valleys being cut up and denuded.

This theory accounts for innumerable facts in the physics of the earth which space would not permit me to enter on, and is, so far as I know, opposed to none.

J. STARKIE GARDNER.

Area of the Land and Depths of the Oceans in Former Periods.

IN a letter to NATURE (p. 54), entitled "Physics of the Sub-oceanic Crust," by my friend, Mr. Jukes-Browne, the following passage occurs:—

"We are at liberty to imagine a time when there was much more land than there is at present, and when all the oceans were comparatively shallow."

I wish to point out that such a condition of things could not obtain if the bulk of the ocean water was the same as now. To get more land, the ocean would have to be *deeper* than now, not shallower. An easy way of conceiving the effect of shallowing the oceans is to mentally lift up the present ocean-floors, the result being an overflow of water and decrease of land area. The only possible way of shallowing the oceans and increasing the area of the land would be to make the ocean-floors perfectly flat, and to surround the continents with vertical walls of rock —in fact, to make the oceans into docks, which nevertheless would exceed two miles in depth.

I pointed out this geometrical fact in "Oceans and Continents"[1]—an article which has provided some of the stock arguments against their fixity. If, therefore, theorists feel it necessary that the land areas should be greater, and the oceans shallower, in former ages, they are bound at the same time to provide some means of decreasing the bulk of the ocean waters. This seems difficult, as other theorists tell us that the amount of water on the globe goes on decreasing, being used up in the hydration of the crust of the earth, and point to the condition of things on the moon as the final stage of our planetary existence.

Distribution of Animals and Plants by Ocean Currents.

SOUS ce titre, vous donniez naguère (vol. xxxviii. p. 245) une correspondance de M. A. W. Buckland concernant divers phénomènes observés à Port-Élisabeth, dans l'Afrique du Sud. Entre autres choses il y était relaté que, vers la fin de l'année 1886, un fruit analogue à celui du cocotier avait été porté par la mer sur le rivage de Port-Élisabeth en même temps que des quantités considérables de pumites ou pierres-ponces.

[1] *Geological Magazine*, 1880, p. 389; also, see letter in same magazine, 1881, p. 335, headed "Subsidence and Elevation."

Le fruit ramassé par un *boy*, "*Il* y porte la dent, fait la grimace. . . . Le moindre ducaton serait bien mieux *son* affaire." Notre *boy* se décide dès lors à porter le fruit au jardinier de "North End Park." Le végétal confié à la terre poussa et donna un arbre, *Barringtonia speciosa*, qui avait atteint 4 pieds de hauteur vers le milieu de l'année 1888.

M. A. W. Buckland émettait l'hypothèse que fruit et pumites, comme aussi quelques poissons et serpents appartenant à des espèces jusque-là inconnues dans le pays, et arrivés en même temps, provenaient des parages de la Sonde, et, à la suite de la grande éruption de Krakatoa en 1883, avaient été portés par les flots jusque sur les rivages de la côte Sud-Africaine.

Il n'y a plus à douter, je crois, de la provenance des pumites. Je n'ai rien à dire au sujet des poissons et serpents. Mais pour ce qui est du fruit de *Barringtonia speciosa*, il me semble qu'on pourrait lui donner une autre origine ou point de départ, et diminuer ainsi de beaucoup la durée de sa traversée sur l'océan.

L'arbre *Barringtonia speciosa* croît, en effet, à Madagascar, où je l'ai vu à Tamatave, sur les bords de la mer. Il ne serait donc point du tout improbable que le fruit porté par les flots à Port-Elisabeth provint de la grande île Africaine. En même temps que je signalais l'arrivée sur nos plages Malgaches des pumites de Krakatoa, en Septembre 1884 et en Février 1885 (*Cosmos*, nouvelle série, No. 12, p. 320), j'envoyais en Europe divers spécimens de ces pumites ramassés sur la plage de Tamatave. Parmi les spécimens adressés à la Société Nationale d'Acclimatation de France s'en trouvait un dans lequel s'était logé une partie de végétal,—une fleur, si je ne me trompe, d'une espèce de *Terminalia*, qui croît aussi à Tamatave sur les bords de la mer (*Bulletin de la Société Nationale d'Acclimatation de France*, Décembre 1884, p. 983).

Un fruit de *Barringtonia speciosa* arbre qui, comme je l'ai fait remarquer, croît au bord de la mer sur la côte orientale de Madagascar, a très bien pu, de même, prendre "passage" sur une pumite ou un banc de pumites atterrées sur la plage Malgache; puis, à la première haute marée, avoir cinglé sur ce "transport" d'un nouveau genre vers la côte Sud-Africaine, poussé par le Courant Indien, jusqu'à son arrivée à Port-Elisabeth, où il a enrichi le "North End Park" d'un nouvel arbre exotique.

Mais, même dans cette hypothèse, le phénomène observé à Port-Elisabeth n'aurait pas un moindre intérêt. L'île de Madagascar y gagnerait de pouvoir être considérée comme une grande "escale," établie par le Dieu Créateur et Ordonnateur des Mondes, pour le service des "Messageries maritimes" de la Nature entre les Archipels de la Malaisie et la côte Sud-Africaine.

Veuillez agréer, Monsieur le Rédacteur, les respectueuses salutations de votre humble serviteur,

PAUL CAMBOUÉ, S.J.,
Missionnaire apostolique à Tananarive.

Tananarive, Madagascar, 15 Octobre.

A Marine Millipede.

BRITISH naturalists, especially such as work on the south coast, will hear with interest that Mr. J. Sinel has lately found in Jersey the very curious *marine* Millipede, *Geophilus submaritima*, Grube (*Verh. d. schles. Gesellsch.*, 1872). Dr. Latzel, of Vienna, tells me that the specimens differ somewhat from the type, and probably constitute a well-marked variety. Some examples were found close to the low-water mark of very low spring tides, where they could not be exposed more than two days in a fortnight.

The Geophilus occurs associated with two or three beetles, of which at least one appears to be new, and with a remarkable Chelifer which is probably identical with *Obisium littorale*, a new species described by Moniez from Boulogne, in this month's *Revue Biologique*, or with the doubtful species *O. maritimum* of Leach (*Zool. Miscellany*, iii. 1817).

Mr. Sinel's crowbar, a tool the naturalist makes too little use of, is doing wonderful service.

December 2.

A Case of Chemical Equilibrium.

DURING some experiments made in connection with a research recently laid before the Royal Society, we came upon an interesting case of chemical equilibrium.

The object of the research was to determine the rate of evolution of oxidizing material liberated, under varied conditions, in a solution containing dilute hydrogen chloride and potassium chlorate. There was also introduced a little starch solution and a small quantity of potassium iodide to serve as an indicator of the completion of a certain amount of work, which was the conversion of a known small weight of sodium thiosulphate into tetrathionate. The completion of this change was marked by the appearance of a blue colour in the liquid. The operation was then repeated.

In these experiments the amount of substances undergoing change, when compared with the total amount present, was so large that the masses of the substances remained practically constant during each experiment.

In such a mixture the condition of equilibrium may be considered to be represented by the following equation:

$$n\mathrm{HCl} + m\mathrm{KClO_3} = m\mathrm{HClO_3} + m\mathrm{KCl} + (n - m)\mathrm{HCl},$$

where n is greater than m.

We may then regard the oxidizing material as being liberated by the reaction of the $(n - m)$ molecules of hydrogen chloride with the m molecules of hydrogen chlorate so liberated. The presence of the m molecules of potassium chloride will produce its specific effect (in this case acceleration) on the rate of reaction. So that out of the n molecules of hydrogen chloride employed only $n - m$ are actively engaged in liberating oxidizing material, the rest having been employed in saline decomposition. If such be the case, it ought to be possible to obtain a similar rate of oxidation by taking m molecules of hydrogen chlorate instead of potassium chlorate, and then reducing the hydrogen chloride used from n to $(n - m)$ molecules. If we then add the m molecules of potassium chloride we should then be able to build up a system similar to what is obtained in the former case as regards saline equilibrium. The following results were obtained by this method of procedure.

The numbers signify millionth gram molecules per c.c., and the rates, R, denote the number of millionth gram molecules of $\mathrm{ClO_3}$ decomposed per minute in each cc.

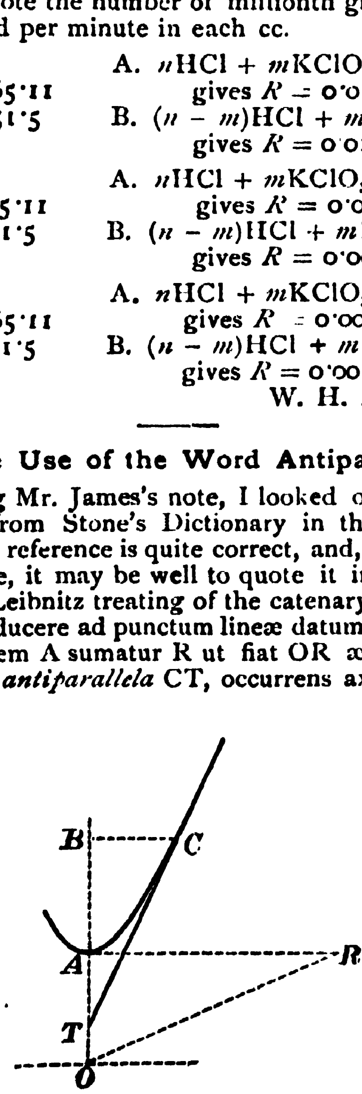
I.	$n = 18 \times 65{\cdot}11$ $m = 6 \times 51{\cdot}5$	A. $n\mathrm{HCl} + m\mathrm{KClO_3}$ gives $R = 0{\cdot}0104$ B. $(n - m)\mathrm{HCl} + m\mathrm{HClO_3} + m\mathrm{KCl}$ gives $R = 0{\cdot}0105$
II.	$n = 15 \times 65{\cdot}11$ $m = 6 \times 51{\cdot}5$	A. $n\mathrm{HCl} + m\mathrm{KClO_3}$ gives $R = 0{\cdot}00554$ B. $(n - m)\mathrm{HCl} + m\mathrm{HClO_3} + m\mathrm{KCl}$ gives $R = 0{\cdot}00555$
III.	$n = 15 \times 65{\cdot}11$ $m = 2 \times 51{\cdot}5$	A. $n\mathrm{HCl} + m\mathrm{KClO_3}$ gives $R = 0{\cdot}00195$ B. $(n - m)\mathrm{HCl} + m\mathrm{HClO_3} + m\mathrm{KCl}$ gives $R = 0{\cdot}00191$

Dover College. W. H. PENDLEBURY.

On the Use of the Word Antiparallel.

AFTER reading Mr. James's note, I looked out the reference quoted by him from Stone's Dictionary in the "Acta Eruditorum." Stone's reference is quite correct, and, as the passage is an interesting one, it may be well to quote it in full. It occurs in an article by Leibnitz treating of the catenary.

"Tangentem ducere ad punctum lineæ datum C; in AR horizontali per verticem A sumatur R ut fiat OR æqualis OB datæ et ipsi OR ducta *antiparallela* CT, occurrens axi AO in T, erit tangens quæsita.



"*Antiparallelas* compendii causa hic voco ipsas OR et TC si ad parallelas AR et BC faciant non quidem eosdem angulos sed tamen, complemento sibi existentes ad rectum, ARO et BCT."

The following quotation is given in Murray's "New English

Dictionary," and is assigned to the year 1660:—"To take the opposite course and to provide our remedy *antiparallel* to their disease." Here it seems intended to convey the idea of "parallel and in the opposite sense."

In Barlow's "Mathematical Dictionary" (1814), the modern meaning is given, and the old error as to the ratios of the segments of the sides of the triangle is pointed out.

In Rees's "Cyclopædia" (1819) the modern meaning is given, but a remark is added that Leibnitz used the word in the sense explained above; as no reference is given, we cannot tell whether the writer meant that he habitually used it or only in the article on the catenary. E. M. LANGLEY.

Bedford.

A Surviving Tasmanian Aborigine.

IN your issue of November 14 (p. 43), you refer to the paper read by Mr. James Barnard before the Royal Society of Tasmania on a Mrs. Fanny Cochrane Smith, who lays claim to be the last surviving aboriginal Tasmanian. Since your note appeared, I have read a report of the paper published in the *Hobart Mercury* of September 10 last, and think my view on the claim may be of some interest to your readers.

Mr. Barnard states that he knew Mrs. Smith forty years ago when she was seventeen years of age, and that during the period which elapsed since then until she called upon him shortly before he wrote his paper, he had not known of her whereabouts. In favour of the claim I can only find that she has, with apparently one exception, always been referred to officially as a pure-bred aborigine, and that Parliament appears to have voted her grants on two occasions (in 1882 and in 1884) on account of her unique position.

The objections to the claim may be briefly summarized as follows:—

(1) From the meagre account given, it appears her hair and complexion are both that of half-castes, and we are not supplied with any other description of her features or stature or peculiarities so as to be able to judge on the question.

(2) Beyond the mere statement as to mutual recognition no evidence is given that the claimant is the same girl Mr. Barnard knew forty years ago at Oyster Cove, nor, indeed, is there anything to show that this woman is the child, or one of the children, referred to by Lieut. Friend in controverting Count Strzelecki's well-known views, which *quasi* fact forms the foundation for the claim.

(3) The woman herself is reported to have no recollection of witnessing, at the age of thirteen, a document sufficiently important to have impressed itself on her memory, and it is somewhat strange that this very document is said to describe her as a half-caste.

It would, no doubt, be interesting were it to be eventually proved that this woman Fanny is a pure-bred aborigine, but for the present Truganina must be considered the last survivor of her race. HY. LING ROTH.

Lightcliffe, November 23.

Brilliant Meteors.

THE brilliant meteor seen at Warwick School and in Cumberland I saw at Folkestone on November 4 a little before 8. It was travelling slowly from north-west to north, about 30° above, and parallel with, the horizon. After travelling some distance it appeared to partly explode, and then went a little farther and burst. At first it was a beautiful green colour, but after it had partly burst it was nearly white. I imagined its colour was through the haze there was in the sky. From what I saw I am certain it would have been a splendid sight had the atmosphere been clear. P. A. HARRIS.

Inchulva, Maidstone, November 27.

LAST night, in clouded moonlight, whilst walking here from Newton by the road over Little Dunnow, my attention was arrested by the glare of what must have been a very bright meteor, seen through clouds which formed a general covering. The quarter in which the light appeared was east by north, at an elevation of about 25°, and it lasted a second and a half. There appeared to be three centres of illumination, but these may have been only thinner portions of the clouds. The time, as nearly as I could get it by comparing my watch by telegraph at the village post office this morning, was 22h. 48m. 45s.

Slaidburn, Clitheroe, December 2. R. H. TIDDEMAN.

REPORT ON THE MAGNETICAL RESULTS OF THE VOYAGE OF H.M.S. "CHALLENGER."

IT will be remembered by readers of the "Narrative of the Voyage of H.M.S. *Challenger*," that Vol. II., published in 1882, contained a report of the magnetic observations made in that vessel in considerable detail. It has, however, been reserved to the present year for a full discussion of the *Challenger* observations and their bearing on our existing knowledge of terrestrial magnetism to be made, and the following is an abstract of the final Report about to be published in Vol. II., "Physics and Chemistry of the Voyage of H.M.S. *Challenger*."

The method of representing the values of the magnetic elements by curves of equal value has, since 1700, when Halley published his map of the declination, found general favour; for in succeeding years we find Mountain and Dodson, Churchman, Yeates, and Barlow, also published maps of the same magnetic element.

In 1819, Hansteen added maps of inclination to the declination for certain epochs, and in 1826 produced a chart of isodynamic lines, revised in 1832.

Following Hansteen, there appeared, in 1840, Gauss and Weber's atlas, the result of calculations from about eighty-four observations distributed over the world, presenting a remarkable approach to the truth, even when viewed in the light of our comparatively extended knowledge of the earth's magnetism in the present day. It may be observed that, if only a fresh magnetic survey of the regions south of 40° S. latitude were now made, a recalculation of the Gaussian constants might be undertaken promising important results.

Between 1868 and 1876 Sir E. Sabine's "Contributions to Magnetism" were read before the Royal Society, forming a series of papers on the magnetic survey of the globe for the epoch 1842·5. Although the maps accompanying these contributions serve as a point of departure for comparison with subsequent maps, an examination of them shows that in Africa and the North and South Pacific Oceans there were large blanks from want of observations

There remained, therefore, a large field for observation, and it will now be shown how largely the *Challenger* Expedition contributed to the filling up of these blanks, and added to our knowledge of the changes going on in the magnetic elements in places visited by previous observers.

The whole of the magnetical results have been embodied with others from every available source in four charts[1] of the magnetic elements, for the epoch 1880, which may prove acceptable to magneticians desirous of noting the changes in the magnetic elements since 1842·5.

The *Challenger* was not an ideal ship in which to conduct magnetic observations at sea, for she was seldom at rest from pitching and rolling, and although the errors in the observations caused by the horizontal component of the ship's magnetism were moderate, and could be eliminated by "swinging" the ship, those proceeding from the vertical component were large, and necessitated a frequent comparison with normal values on land.* But by discussing fully a series of observations made in numerous places in both hemispheres where no trace of local magnetic disturbance could be found, the magnetic condition of the ship was readily determined for any period of the voyage. As a consequence of this, normal values of the magnetic elements could be obtained in the neighbourhood of places known or suspected of being affected by local magnetic disturbance, and the amount of such disturbance measured with considerable accuracy.

This method of detecting local magnetic disturbance,

[1] Note published with the "Report of the Scientific Results of the Voyage of H.M.S. *Challenger*," Physics and Chemistry, Vol. II., Part VI.

was applied to the solitary islands of the ocean visited by the *Challenger*, and the following are some of the principal results.

At Madeira there was a difference of 7½° in the observed inclination between observations made at 1 foot and 3½ above the ground; and at Santa Cruz, Tenerife, the inclination was 2½° in excess of the normal observed in the ship.

It was at Bermuda, however, that the most remarkable results were obtained. For some years previously, observers in different parts of the group had obtained very different values of the declination, and our men-of-war when swinging for deviations of the compass had found constant errors for every direction of the ship's head which were peculiar to Bermuda. It could only, therefore, be by a properly equipped expedition like that of the *Challenger*, and systematic observation, that the immediate cause of all this local magnetic disturbance could be traced.

For this purpose the declination was observed at seventeen stations, the inclination at ten, and the intensity at seven. Combining these observations with others made by previous observers, it was found that between the Governor's house at Mount Langton and the lighthouse on Gibb's Hill, there is a disturbing magnetic focus attracting the north-seeking end of the needle with a force considerably in excess of that due to the position of Bermuda on the earth considered as a magnet. The normal values of the magnetic elements were obtained by swinging the ship at sea 15′ south of the green outside the dockyard. The difference between the observed declination at Clarence Cove and Barge Island was 5° 44′. The greatest difference in the inclination was 1° 47′, and in the vertical force + 0·314 (Brit. units).

Local magnetic disturbances were also noted at St. Vincent, Cape de Verde Islands, Tristan d'Acunha, Kerguelen Island, Sandwich Islands, Juan Fernandez, and Ascension, but not at St. Paul Rocks.

By applying the same method of obtaining normal values at sea, and observing on other adjacent solitary islands such as St. Helena, similar effects result, and the following general conclusions seem to be supported by fact with regard to local magnetic disturbance:—

(1) That in islands north of the magnetic equator, the north-seeking end of the needle is generally attracted vertically downwards, and horizontally towards the higher parts of the land; (2) south of the magnetic equator the opposite effects are observed, the north-seeking end of the needle being repelled: in both cases by an amount above that due to the position of the island on the earth considered as a magnet.

Interesting as these conclusions may possibly be from a scientific point of view, they are of real importance in practical navigation. Navigators have asserted that their compasses were disturbed when passing the land in certain parts of the world. We learn from the *Challenger* observations that within 5 feet from the soil the greatest magnetic disturbance did not exceed 3° in the declination and 2½° in the inclination. Remembering the law of magnetic attraction and repulsion, it is impossible that a compass in such case could be disturbed in a vessel passing the land at the ordinary distance. In point of fact, it has been shown that it is to submerged magnetic land comparatively near the ship's bottom that the disturbance of the compass is due. The remarkable instance at Cossack in North-West Australia may be cited in support of this conclusion. Thus in H.M.S. *Meda*, sailing on a line of transit of two objects on land for a quarter of an hour in 8 fathoms of water, it was found that the compass was steadily deflected 30°, no visible land being nearer than 3 miles.

Great as the gain must be to the navigator to be thus warned of a formidable danger in certain places, it also lays upon him the important duty of being on his guard against similar disturbances elsewhere, reporting any new discoveries as he would a rock or shoal.

Large as was the *Challenger's* contribution to the magnetic charts for 1880, it will be readily understood that it required considerable reinforcement from other sources, as their construction was dependent on observation alone. Every available observation between the years 1865–87 was utilized. Beyond the published sources of information on this subject may be mentioned the observations made on the east coast of Africa by the officers of H.M.S. *Nassau* in 1874–76, and on the west coast of Australia in 1885–86 by H.M.S. *Meda*. Also the sea observations between Australia and Cape Horn of the declination in H.M.SS. *Esk*, *Pearl*, and *Thalia*, between 1867–87, not forgetting those of the New Zealand Shipping Company's vessels in 1885–86.

To combine this twenty years' observation usefully, a somewhat extended knowledge of the distribution and amount of secular change became a necessity. Generally speaking, it is only at fixed observatories that this element of terrestrial magnetism is known with precision, for, as already shown, observations a few feet apart often give very different results. In the more frequented parts of the earth this secular change is approximately known, especially in the United States, where valuable work has been accomplished.

One great object of the voyage of the *Challenger* was to visit certain unfrequented positions where previous observers had been, rather than the beaten tracks. Thus Ross's position of 1840 on St. Paul Rocks was visited, and the secular change during thirty-three years obtained. Then Tristan d'Acunha, an important station situated in mid-ocean, rarely visited for magnetic purposes. At Kerguelen Island, another of Ross's positions, observations of all three principal magnetic elements were made, and the secular change found approximately.

In the Indian Ocean generally, north of 30° S., the secular change of the declination rarely exceeds 1′ annually, but at Kerguelen Island the westerly declination is increasing at least 5′ annually.

It was, however, from two positions on the homeward voyage that the most novel and remarkable values of the secular change were obtained—Sandy Point, Magellan Straits, and the Island of Ascension, with its adjacent waters.

At Sandy Point, with the horizontal force nearly stationary, and the declination decreasing 3′ annually, it was hardly suspected until 1876, when the *Challenger* visited the place, that the inclination was apparently changing 11′ annually. Comparing the *Challenger's* results by swinging near the Island of Ascension with Sabine of 1842·5, the following values of the secular change are obtained: declination increasing 8′ annually; south inclination increasing 14′.

From these results the notable fact is made evident, that the north-seeking end of the needle is found to be moving in opposite directions, downwards at Sandy Point, and more strongly upwards at Ascension. Extending the inquiry into the surrounding seas and countries, it was found that these opposite movements of the needle were not confined to the spots where they were discovered.

The author of this Report, after having discussed his collection of a large number of observations of the magnetic elements for all parts of the world—in many cases extending over several years—obtained approximate values of their secular change for the epoch 1840–80.

These several values were weighted according to their relative accuracy, and entered on maps against the places of observation. Lines of equal value were then drawn for each element, and the following general results obtained with regard to the movements of the north-seeking end of the needle.

1. *Declination.*—The principal lines of little or no change were found to take the course from St. John's,

Newfoundland, to the West Coast of Africa, near Cape de Verde, emerging near Cape Palmas, and then to Cape Town; thence curving upwards near Mauritius, downwards south of Cape Leeuwin, again upwards through Adelaide and Cape York to the vicinity of Hong Kong. A second line passed from Sitka through the western portion of the continent of North America, striking South America near Callao, then following the trend of the coast to a point near the western entrance to Magellan Strait.

The foci of maximum value of change were found: (1) between Scotland and Norway, change about 9′ annually, needle moving eastward; (2) on the east coast of Brazil, needle moving westward about 8′. Minor foci were also found: one near Kerguelen Island, the other in the South Pacific. Another focus apparently exists in Alaska. The general tendency was for the values of the change to decrease gradually from the foci to lines of no change.

2. *Inclination.*—Similarly to that of the declination, there are lines of no change, two principal foci of maximum secular change, but only one minor focus. The lines of no change are not so clearly defined as those for the declination, data being still wanting. The principal foci of maximum change in the inclination were found: (1) near the Gulf of Guinea, between Ascension and St. Thomé, which may be called the Guinea focus. Here the north-seeking end of the needle was moving *upwards* about 15′ annually. (2) in the latitude of Cape Horn, and about 80° W. long. This may be called the Cape Horn focus, and the annual change was 11′, needle being drawn *downwards*. It must be distinctly understood that both the positions and values of the change are only approximate, and only the general features in the angular movement of the freely suspended needle are to be accepted, as clearly shown by this investigation.

3. *Magnetic Intensity.*—In the horizontal force, the annual change (B.U.) was about −0·002 near Cape Horn, whilst between Valparaiso and Monte Video the focus of greatest change was about −0·017. Again, on the west coast of Portugal a focus of +0·009 (B.U.) occurred.

Turning to the vertical component of the earth's intensity, some remarkable results were observed. At the Cape Horn focus an annual change of 0·055 (B.U.) was found in the vertical force, the north-seeking end of the needle being drawn *downwards*, the change diminishing in value until the zero line extending from Callao across the American continent to the west coast between Bahia and Rio de Janeiro, and then taking a southeasterly course north of Tristan d'Acunha, was reached. Northward and eastward of this zero line there were found increasing values in the annual change in the *upward* vertical force acting on the north-seeking end of the needle until the Guinea focus was reached, where its full value was increasing 0·025 annually. From the Guinea focus to Northern Europe, Asia, and the Atlantic seaboard the change gradually decreased in amount. There were signs of minor movements in the north-seeking end of the needle in China, Mexico, and the United States.

One of the chief factors in the compilation of the previously mentioned maps of the three elements for the epoch 1880 were the observations taken in the *Challenger*, and these were reduced to the common epoch by means of the investigation of annual change to which reference has just been made.

It may be truly said that the *Challenger's* track was studded with magnetic observations. After successfully traversing the Atlantic Oceans in varying directions, the three magnetic elements were obtained by swinging, in probably the most southerly position since the days of Ross in the *Erebus* and *Terror*, in lat. 63° 30′ S., and long. 90° 47′ E. But the most valuable part of the contributions to terrestrial magnetism obtained in the *Challenger* were the observations made in the North and South Pacific. The route lay from Wellington, N.Z., to Tongatabu, and Fiji, from the Admiralty Islands to Japan, and thence in mid-ocean from nearly 40° N., through the Sandwich Islands and Tahiti to 40° S., nearly at right angles to the curves of equal magnetic inclination.

During the voyage much experience was gained as to the usefulness of the Fox circle as an instrument for use on board ship at sea, the general result being that valuable work may be done with it if frequently compared with the absolute instruments on land, and the instrument mounted on a gimbal stand prepared to withstand the vibrations caused by the engines of the vessel.

Although on the general question of the secular change of the magnetic elements much has been already written in this Report, there yet remain some important points which demand further discussion.

As to the causes of the secular change various hypotheses have been advanced. Thus in the early part of the last century, Halley considered the change was chiefly caused by a terella with two poles or foci of intensity rotating within and independently of the outer shell of the earth, which also possessed two foci of intensity, the axes of the two globes being inclined one to the other but having a common centre.

Again, Hansteen at the beginning of the present century concluded that there are four poles of attraction, and computed both the geographical positions and the probable period of the revolution of this dual system of poles or points of attraction round the terrestrial pole.

In later years Sabine considered the secular change to be caused by the progressive translation of the point of attraction at present in Northern Siberia, this point of attraction resulting from cosmical action. Walker also agreed with Sabine as to the cosmical origin of the change.

Later still, Balfour Stewart gave reasons for attributing the secular variation to the result of solar influence of a cumulative nature.

Keeping in view these hypotheses, and recalling the chief results of observation during recent years, how do they accord?

Observation generally points to the fixity of the magnetic poles—or two limited areas where the needle is vertical—in respect to the geographical poles. Again, in Siberia there is little or no apparent translation of the greatest point of attraction in that region, and the North American focus of intensity is probably at rest.

Thus the results of observation in recent years are not favourable to hypotheses founded on the translation of the poles or foci of magnetic intensity.

Let the terms blue and red magnetism be adopted, and the movements of the red, or north-seeking, end of the needle alone be considered.

The question arises, What have recent observations offered us instead? They tell us that near a line drawn from the North Cape of Norway across the Atlantic to Cape Horn lie some of the foci of greatest known secular change. It was also found that at the Cape Horn focus of vertical force the needle was moving downwards, or there was the equivalent to a blue pole of increasing power of attraction, the freely suspended needle being attracted towards it over an extended region around. At the Guinea focus there was the equivalent to a red pole of increasing power of repulsion, the freely suspended needle being repelled over an extended region of undefined limits. The action of these two poles apparently combine to produce a focus of considerable angular movement in the horizontal needle near Brazil.

In China there is a minor blue pole of increasing power attracting the needle over a large area.

With apparently small secular changes in Siberia, and the horizontal needle moving somewhat rapidly to the eastward at the focus of change in the declination in the German Ocean, and similarly to the westward in Alaska,

analogy points to the probability of there being a decrease in the vertical force in the high latitudes of North America, or the equivalent to a red pole of increasing power repelling the needle for a large area around it.

The variations in the vertical force at and about these poles or foci of attraction and repulsion at different epochs are not yet sufficiently determined, but if the hypothesis of translation be given up, it is not unreasonable to suppose that the secular changes in the declination and inclination are chiefly dependent upon changes in the relative power of these poles.

No satisfactory explanation has yet been given of the remarkable changes in the earth's magnetic force as measured on its surface, and suggestions are only possible in the present instance.

The voyage of the *Challenger* has shown that local magnetic disturbance is found in the solitary islands of the sea, although surrounded by apparently normal conditions, similar to that on the great continents. It has also been suggested that the magnetic portions of these islands causing the disturbance may possibly "have been raised to the earth's surface from the magnetized portion of the earth forming the source of magnetism," and tending to prove Airy's conclusion "that the source of magnetism lies deep."

In view, therefore, of past geological changes and those now in progress, it may fairly be conceived, not only that large changes have likewise occurred in the distribution of the magnetic portions of the earth appearing here and there on the surface and producing local magnetic disturbance, but that there are others of a more progressive character below the earth's surface which are only made manifest by the secular change observed in the magnetic elements. This conception with regard to secular change is not intended to exclude the view that solar influences may have a small share in producing the observed phenomena.

In conclusion, it may be remarked that they who would fully see the substantial gains to terrestrial magnetism which have been obtained by the voyage of the *Challenger* must refer to the original of this abstract Report, with its plates and charts of the magnetic elements. Subsequent research may add to, qualify, or reverse the conclusions drawn from the observations, but the observations will probably retain a long-abiding value to magneticians. E. W. CREAK.

ON THE SUPPOSED ENORMOUS SHOWERS OF METEORITES IN THE DESERT OF ATACAMA.

IT is now universally acknowledged both that meteorites come from outer space and that shooting-stars, whatever they are, have an extra-terrestrial origin. It is further asserted that a meteoritic fireball and a shooting-star are only varieties of one phenomenon. Indeed, after it is once granted that a meteoritic fireball is produced by the passage through the terrestrial atmosphere of a dense body entering it with planetary velocity from without, and that shooting-stars have an extra-terrestrial origin, it is a very fair assumption that a shooting-star is likewise a dense body rendered luminous during its atmospheric flight.

One great objection to this assertion is that, again and again, showers of hundreds of thousands of shooting-stars have taken place, during which no heavy body has been observed to reach the earth's surface. The only known case of the arrival of a meteorite during a shooting-star shower has been that of Mazapil, on November 27, 1885, and that single coincidence may possibly be the result of accident. A sufficient explanation of this difficulty, however, is to be found in the small size of the individuals which produce the appearance of a shooting-star shower. That the individuals are really minute is proved by the fact that, while the total mass of a large swarm, like that producing the November meteors, is so small that there is no perceptible influence on the motion of the planets, the number of separate individuals is almost infinite. It is established that the Leonid swarm must be hundreds of millions of miles in length, and some hundreds of thousands of miles in thickness; and in the densest part of the Bielid swarm, passed through in 1885, the average distance of the individuals from each other was about twenty miles.

Further, it is now acknowledged that comets are themselves meteoritic swarms, and Mr. Lockyer has lately brought forward spectroscopic evidence that the fixed stars and the nebulæ are similar to comets in their constitution.

The question therefore immediately presents itself, Is the size of a meteoritic shower, on reaching the earth's surface, ever comparable with that of a meteoritic swarm, as manifested by a shower of shooting-stars?

During the present century nearly 300 meteoritic falls on the earth's surface have been observed, and on only a single date, namely August 25, 1865, has there been observed a fall on two distant parts of the earth on the same day. On that date stones fell at Aumale in Algeria, and at Sherghotty in India; but as the times of fall differed by about eight hours, and the stones arrived from different directions, it is more than probable that the coincidence of date was accidental. Hence we must infer that a swarm of meteorites, as far as actual observation of tangible objects goes, far from being hundreds of millions of miles long, with individuals a few miles apart, is a comparatively small group, separated from its neighbours, if it has any, by a distance comparable with the earth's diameter.

The extent of surface over which meteoric stones have been picked up after some of the best known and most widely spread falls is given in the following list:—

Limerick, 3 miles long.
Mocs, 3 miles by 0·6 mile.
Butsura, 3 miles by 2 miles.
Pultusk, 5 miles by 1 mile.
L'Aigle, 6 miles by 2·5 miles.
Barbotan, 6 miles long.
West Liberty, 7 miles by 4 miles.
Stannern, 8 miles by 3 miles.
Knyahinya, 9 miles by 3 miles.
Weston, 10 miles long.
Hessle, 10 miles by 3 miles.
New Concord, 10 miles by 3 miles.
Castalia, 10 miles by 3 miles.
Khairpur, 16 miles by 3 miles.

As far as I have yet been able to ascertain, the greatest observed separation has been sixteen miles. In the case of Macao, Cold Bokkeveldt, and Pillistfer, wider spreads have been chronicled, but later information has shown the inaccuracy of the earlier statements.

As regards the meteoric irons, there have only been nine observed falls since the year 1751: in seven of them only a single mass was found; in the remaining two there was in each case a couple of masses, not more than a mile apart. There is thus no recorded instance of an observed shower of meteoric iron. The most convincing proof of the actuality of such showers is furnished by the masses which have been found in the Valley of Toluca, in Mexico; their existence had been chronicled as early as the year 1784, yet in 1856 it was still possible to collect as many as sixty-nine. When etched, they show the Widmanstätten figures in the most excellent way, and in their characters they are typical meteorites. Belonging, as they do, to a single type, they lead to the conviction that they are the result of a single shower. But the region over which the fall took place is not large; the

length of it is said to have been only about fourteen miles.

It is very probable, though not conclusively proved, that large meteoritic showers of stones, like those of Pultusk and L'Aigle, reach the terrestrial atmosphere as swarms of isolated bodies; still, we must have regard to the fact that a mass is much fractured during its passage through the air by reason of the enormous pressure and the violent change of temperature. In the case of the Butsura fall, for example, it was conclusively established that stones picked up some miles apart must originally have formed part of a stone disrupted during the atmospheric flight.

It is a question of a certain amount of interest as to whether there is any evidence of the actual fall of a shower of meteorites over a large extent of the earth's surface.

Such evidence has long been supposed to be furnished by the plentiful occurrence of meteorites in the Desert of Atacama, a term applied to that part of Western South America which lies between the towns of Copiapo and Cobija, about 330 miles distant from each other, and which extends inland as far as the Indian hamlet of Antofagasta, about 180 miles from the coast.

The generally received impression as to the occurrence of meteorites in this desert is well illustrated by the following statement of M. Darlu, of Valparaiso, read to the French Academy of Sciences in 1845:—

"For the last two years I have made observations of shooting-stars during the nights of November 11–November 15, without remarking a greater number than at other times. I was led to make these observations by the fact that in the Desert of Atacama, which begins at Copiapo, meteorites are met with at every step. I have heard, also, from one who is worthy of trust, that in the Argentine Republic, near Santiago del Estero, there is—so to say—a forest of enormous meteorites, the iron of which is employed by the inhabitants."

A study of the literature indicates that "the forest of enormous meteorites" near Santiago del Estero, understood by Darlu as significative of infinity of number, is really a free translation of a native statement "that there were several masses having the shape of huge trunks with deep roots," and that not more than four, or perhaps five, masses had really been seen in the Santiago locality at the time of Darlu's statement. There is a similar misunderstanding relative to the Atacama masses: it is clearly proved that, at a date long subsequent to 1845, the Desert was virtually untrodden and unexplored. In Darlu's time it was only crossed along definite tracks by Indians travelling between San Pedro de Atacama and Copiapo, and between the inland Antofagasta and the coast. In fact, it is established that the only Atacama meteorites then in circulation were all got from a single small area, three or four leagues in length, in the neighbourhood of Imilac, one of the few watering-places on the track between San Pedro and Copiapo.

Since that time the discovery of rich silver-mines in the centre of the Desert, and the working of the nitrate deposits, have led to vast changes; the Desert has been more or less closely examined, and other meteoritic masses have been found. Still, the number of meteorites yet discovered, distinct either in mineralogical characters or locality, is shown to be, at most, thirteen.

One of them, Lutschaunig, is distinct from all the rest as being a chondritic stone; a second, Vaca Muerta, likewise differs from all the others in that it consists of nickel-iron and stony matter, both in large proportion; a third, Imilac, is a nickel-iron with cavities, like those of a sponge, filled with olivine; a fourth, Copiapo, is a nickel-iron with irregularly disposed angular inclosures of troilite and stony matter; the remaining nine consist of nickel-iron, virtually free from silicates, some of them showing no Widmanstätten figures when etched, others showing excellent figures more or less differing in character.

Now, in every meteoritic shower yet observed, the individuals which have fallen simultaneously have been found to belong to a common type. Hence, it is reasonably certain that several distinct meteors are represented in the Desert, and that the above masses are the result of several falls; and this being accepted, the assertion of simultaneity of fall of two or more masses on the purely geographical ground that they have been found in the same Desert, can be allowed no great weight.

But have masses belonging to any one of the above types been found scattered over a part of the Desert so extensive as to indicate a meteoritic fall more widely spread than any of those actually observed? A critical examination of the cases in which such an enormous spread has been asserted proves that the evidence is quite unsatisfactory. The results may thus be summarized:—

(1) *Lutschaunig.*—This was a single stone.

(2) *Vaca Muerta.*—The masses were in great abundance distributed over a small area. But fragments undoubtedly belonging to this type have been brought from two other places far distant from the main locality. Very cogent evidence is brought forward to prove that the said fragments must have been *carried* to those places—the Jarquera Valley and Mejillones—from Vaca Muerta itself.

(3) *Imilac.*—An examination of all the known literature indicates that the whole of the fragments belonging to this type have been got from the immediate neighbourhood of Imilac. Caracoles, Potosi, and Campo de Pucará, from which specimens, belonging to this type, have been brought, are shown to be on regular lines of traffic starting from the Atacama coast. It is further shown that Imilac specimens were in great request, and were certainly carried to very distant places along such lines of traffic.

(4) *Copiapo.*—It is conclusively proved that the two localities, upwards of 400 miles apart, for meteoritic masses belonging to this type, result from a mere interchange of labels, and that all the masses probably came from a single place.

(5–13) There is no satisfactory evidence furnished by similarity of type for any of the meteoric irons being part of a widespread shower.

It is thus clear that the meteorites of the Desert of Atacama afford absolutely no proof that enormous meteoritic showers have ever reached the earth's surface.

The general dryness of the air of the Desert, and the rarity of rain, have been sufficient to ensure the preservation of masses which have fallen in the course of many centuries unto a time when an exploration of a large extent of the Desert has taken place.

That the meteoritic masses are far from being so plentiful as has been imagined is conclusively proved by the experience of Mr. George Hicks, one of the earliest explorers of the 23rd and 24th parallels; although much interested in their occurrence, he never found a mass himself, and he only obtained his first specimen after years of persevering inquiry from the Indians.

Detailed information relative to the Atacama meteorites, with a description and map of the Desert, will be found in the recently published number of the *Mineralogical Magazine.* L. F.

EARLY EGYPTIAN CIVILIZATION.

ALTHOUGH the paintings in the tombs of Memphis, of Beni Hasan, and of Thebes, have preserved to us the knowledge of much of the civilization of Egypt, yet hitherto we have handled but few examples of the im-

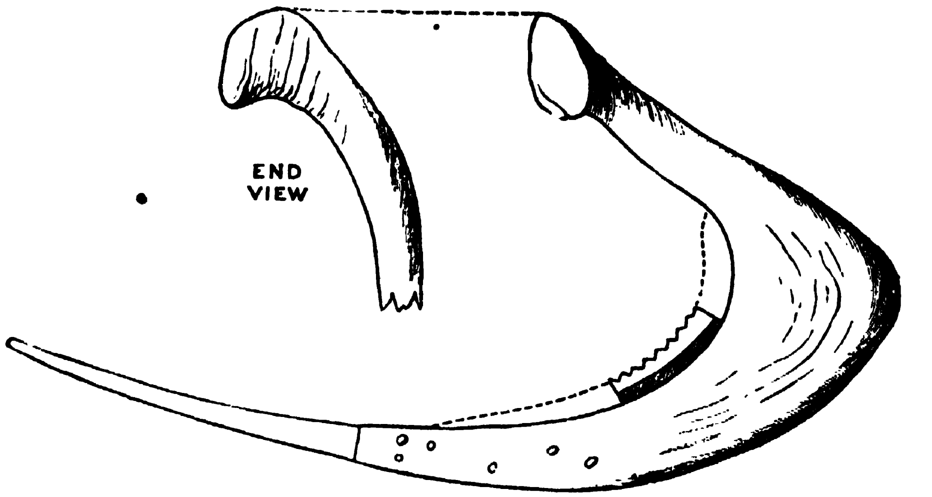
plements used, and those are mostly undated. Broadly speaking, the three sites just named represent respectively the Old Kingdom before 3400 B.C., the Middle Kingdom about 2600 B.C., and the New Kingdom from 1600 B.C.; and though debarred from scientific work in these richest districts of Egypt—owing to national jealousies—I have been fortunate enough to discover two small towns, each only occupied for a couple of centuries, which have thus revealed the works of the Middle and New Kingdoms with chronological exactness. Beside the Egyptian interest of these places, they are of prime importance for Mediterranean history, having been colonies of foreign workmen.

These towns are one on each side of the entrance to the Fayum province, fifty miles south of Cairo. The northern town, now called Kahun, was built for the workmen employed by Usertesen II., for his pyramid and temple, about 2600 B.C. The southern town, now called Gurob, was founded by Tahutmes III., and destroyed by Merenptah, thus lasting from about 1450 to 1190 B.C. Obtaining thus two sites of different ages, close together, we can be certain that all differences are due entirely to time and not to locality. The change in an interval of 1200 years is most marked. Of the pottery, scarcely a single type of form or material is alike in the two periods; of the many varieties of beads of stone and glazed ware, hardly one was continued; the metal tools are every one changed in form; and the use of flints had practically died out. For the first time we are able to trace the definite and decided changes in all the products of two ages so remote. The idea that Egypt was changeless is only due to our lack of knowledge; not only fashions changed—every few years in minor details—but radical rearrangements were made from age to age in the manufactures.

The twelfth dynasty town—Kahun—is the more important, and we will briefly note some of its products. Flint working was carried to a high pitch, the thin flat knives being flaked with much skill: but alloys of copper were also in use, and show ability in their casting and hammering, a thin bowl being wrought out of one piece. We find, then, flint and metal side by side, the flint being the commoner material, but yet influenced in its forms by the types of metal tools. Moreover, we now see the use of the numerous flint saws, formed of serrated flakes; many of them have black cement upon them, and one was found remaining in its socket in a wooden sickle (Fig. 1).

Beside hatchets, adzes, and chisels of bronze, we find needles, barbed and unbarbed fish-hooks, netting-needles, and knives of the straight-backed type. Among wooden tools are hoes, rakes, grain-scoops, a brick-mould, plasterers' floats, bow-drills, plummets, &c. Perhaps the most important of all is a fire-stick, on which five burnt holes

FIG. 1.



Wooden sickle with flint saw (twelfth dynasty).

remain where fire has been drilled by a rotating rod: the drilling was begun by hacking a groove in the side of the stick, down which the heated wood powder might run, until it caught alight. This shows, for the first time, how the Egyptians obtained fire: and familiar as they were with the bow-drill, they doubtless used it for the fire-stick. A very interesting point is the origin of the shoe from the sandal. Two sandal-shoes have been found; both with toe and heel straps, but with an upper of leather across the foot. Tops, tip-cats, clay toys, dolls with jointed limbs, and game boards, were all in use. Among a large number of papyri that I found are two wills, one of which is a recital of a will and a settlement, duly witnessed. The provisions show that the later law of Greek times was much the same in matters of descent as it was two thousand years earlier. On receiving family property the man settles it on his wife; she has a life interest in the dwellings, and may divide all the property among their children at her discretion. The man's official position he left to his son. A guardian was also appointed, excluding the eldest son from that duty. Some numerical notes concerning fractions are also found; and all these papyri are in course of study by Mr. F. L. Griffith.

On turning to the later town—Gurob—of about 1300 B.C., we find that the art of flint working was lost; only a few rude leaf-shaped flakes (totally different from the earlier forms) and some little saw-flakes remain, and these are scarce. Thus we may date the fall of fine flint manufacture in Egypt to about 2000 B.C.; though rude flakes continued to be used till late Roman times, and more abundantly in poorer ages. Bronze tools were much modified; hatchets and chisels less finely formed, knives always double edged, fish-hooks not barbed, and punched metal rasps were brought in. Bronze working reached a high level in the making of two large pans, 14 and 9 inches across, exquisitely wrought with difficult curves, and so thin that they can be still bent in and out by the fingers. Glass ornaments were commonly used, though not found in the earlier town. The plain beads of fine blue, violet, &c., belong to about 1300 B.C.; while the coarser beads of black, yellow, green, brown, and white, with eye-patterns, are about a century later.

The presence of foreigners in both of these towns is shown by the weights discovered, which are—with scarcely an exception—of foreign standards, foreign forms, or foreign materials. A commercial intercourse must therefore have been kept up between these foreign colonies and the Mediterranean. Beside this evidence we find at Gurob the burials of one of the Tursha or Turseni (from Asia Minor), and a Hittite; foreign art is seen in a mirror handle with the Phœnician Venus, and a wooden figure of a Hittite; and foreign complexions are shown by the light hair found on some of the bodies. A very strong Mediterranean influence appears in the quantity of pottery

identical with the earliest styles found at Mykenæ, at Thera, and at Mytilene; and we are now able to date those stages of early culture in the Greek lands to 1300 B.C., a fixed point of the greatest value.

The most novel discovery of all is the presence of apparently alphabetic signs in use in both towns (Fig. 2), and by all the circumstances amply guaranteed to be of about 2500 B.C. and 1300 B.C. Our existing theories of alphabetic development require us to suppose that the Phœnician letters were established before 2000 B.C.; as the Egyptian writing from which De Rougé derived them, was extinct after that date; and the Cypriote syllabic signs must be older. Thus, though no known inscriptions can be placed before about 900 B.C., yet the forms must have started about the same period as that of the first of these towns, Kahun. The conditions that we find, therefore, of a great variety of signs in use, many of which have not survived, while others have drifted apart into many different alphabets, are just what might be expected at

Fig. 2.

Signs incised on pottery of the twelfth dynasty (Kahun).

Signs on pottery of the eighteenth to nineteenth dynasty (Gurob).

these early times. The apparent connection of these signs with some of the mason's marks of Egypt suggests that they may have been adopted by the foreign workmen from their Egyptian fellow-labourers; and the very lack of literary education among such men would lead to their forming alphabets of their own from such materials. We have at least now obtained two well-defined stages, between the finished and segregated alphabets of the period of known inscriptions, of 900 B.C. downward, and the original elements of Egyptian hieroglyphs, hieratic, mason's marks, and perhaps Hittite and cuneiform characters, from which the alphabets were evolved. To discuss the historical descent of the signs, and to form a continuous theory of them, will need much discussion, and more materials. Meanwhile, my work will lie in the complete gathering in of what may still remain in these towns. A full account and drawings of every sign and every object of importance found this year will appear in a few months. W. M. FLINDERS PETRIE.

MR. STANLEY'S GEOGRAPHICAL DISCOVERIES.

THIS week an interesting letter from Mr. Stanley to Colonel Grant has been published. It is dated, "Villages of Batundu, Ituri River, Central Africa, September 8, 1888." Speaking of Lake Albert, Mr. Stanley says:—

"When on December 13, 1887, we sighted the lake, the southern part lay at our feet almost, like an immense map. We glanced rapidly over the grosser details—the lofty plateau walls of Unyoro to the east, and that of Baregga to the west, rising nearly 3000 feet above the silver water, and between the walls stretched a plain—seemingly very flat—grassy, with here and there a dark clump of brushwood—which as the plain trended south-westerly became a thin forest. The south-west edge of the lake seemed to be not more than six miles away from where we stood—by observation the second journey I fixed it at nine miles direct south-easterly from the place. This will make the terminus of the south-west corner at 1° 17′ N. lat. By prismatic compass the magnetic bearing of the south-east corner just south of Numba Falls was 137°, this will make it about 1° 11′ 30″ N. lat. A magnetic bearing of 148° taken from N. lat. 1° 25′ 30″ about exactly describes the line of shore running from the south-west corner of the lake to the south-east corner of the Albert. Baker fixed his position at N. lat. 1° 15′, if I recollect rightly. The centre of Mbakovia Terrace bears 121° 30′ magnetic from my first point of observation, this will make his Vacovia about 1° 15′ 45″, allowing 10° west variation.

"In trying to solve the problem of the infinity of Lake Albert as sketched by Baker, and finding that the lake terminus is only four miles south of where he stood to view it 'from a little hill,' and on 'a beautifully clear day,' one would almost feel justified in saying that he had never seen the lake. But his position of Vacovia proves that he actually was there, and the general correctness of his outline of the east coast from Vacovia to Magungo also proves that he navigated the lake. When we turn our faces north-east, we say that Baker has done exceedingly well, but, when we turn them southward, our senses in vain try to penetrate the mystery, because our eyes see not what Baker saw. When Gessi Pasha first sketched the lake after Baker, and reduced the immense lake to one about ninety miles long, my faith was in Baker, because Gessi could not resolve by astronomical observations the south end of the lake. When Mason Bey —an accomplished surveyor—in 1877 circumnavigated the lake, and corroborated Gessi, then I thought that perhaps Mason had met a grassy barrier or sandbank overgrown with sedge and ambatch, and had not reached the true beyond, because he admitted that he could not see very far from the deck of his steamer, my faith still rested in Baker; but now, with Lieutenant Stairs, of the Royal Engineers, Mr. Mounteney Jephson, Surgeon Parke, Emin Pasha, Captain Casati, I have looked with my own eyes upon the scene, and find that Baker has made an error.

"I am somewhat surprised also at Baker's altitudes of Lake Albert, and the 'Blue Mountains,' and at the breadth attributed by him to the lake. The shore opposite Vacovia is ten and a quarter miles distant, not forty or fifty miles; the 'Blue Mountains' are nothing else but the west upland—the highest cone or hill being not above 6000 feet above the level of the sea, not 7000 or 8000 feet high. The altitude of Lake Albert by aneroid and boiling-point will not exceed 2350, not 2720, feet.

"And last of all, away to the south-west where he has sketched his 'infinite' stretch of lake, there rises, about forty miles from Vacovia, an immense snowy mountain—a solid square-browed mass with an almost level summit between two lofty ridges. If it were 'a beautifully clear day' he should have seen this, being nearer to it by thirteen geographical miles than I was."

Of the snowy Mountain, Mr. Stanley writes as follows:—

"My interest is greatly excited, as you may imagine, by the discovery of Ruwenzori—the Snowy Mountain—a possible rival of Kilimanjaro. Remember that we are in north latitude, and that this mountain must be near on the equator itself, that it is summer now, that we saw it in the latter part of May, and that the snow-line was about (estimate only) 1000 feet below the summit. Hence I conclude that it is not Mount Gordon Bennett, seen in December 1876 (though it may be so), which, the natives said, had only snow occasionally. At the time I saw the latter, there was no snow visible. It is a little further east, according to the position I gave it, than Ruwenzori.

"All the questions which this mountain naturally gives

rise to will be settled, I hope, by this Expedition before it returns to the sea. If at all near my line of march, its length, height, and local history will be ascertained. My young officers will like to climb to the summit, and I shall be glad to furnish them with every assistance."

At the time when this letter was written, Mr. Stanley was uncertain as to the destination of the streams flowing between "the two Muta Nzigés":—

"Many rivers will be found to issue from this curious land between the two Muta Nzigés. What rivers are they? Do they belong to the Nile or the Congo? There is no river going east or south-east from this section, except the Katonga and Kafur, and both must receive, if any, but a very small supply from Gordon Bennett and Ruwenzori. The new mountain must therefore be drained principally south and west. If south, the streams have connection with the Lake South; if west, the Semliki tributary of Lake Albert, and some river flowing to the Congo must receive the rest of its waters. Then, if the Lake South receives any considerable supply, the interest deepens. Does the lake discharge its surplus to the Nile or to the Congo? If to the former, then it will be of great interest to you, and you will have to admit that Lake Victoria is not the main source of the Nile; if to the Congo, then the lake will be the source of the River Lowwa or Coa, since it is the largest tributary to the Congo from the east between the Aruwimi and the Luama. For your comfort I will dare venture the opinion even now that the lake is the source of the Lowwa, though I know nothing positive of the matter. But I infer it, from the bold manner in which the Aruwimi trenches upon a domain that anyone would have imagined belonged to the Nile. It was only ten minutes' march between the head of one of its streams to the crest of the plateau whence we looked down upon the Albert Nyanza.

"From the mouth of the Aruwimi to the head of this stream is 390 geographical miles in a straight line. Well, next to the Aruwimi in size is the Lowwa River, and from the mouth of the Lowwa to the longitude of Ugampaka post in a direct line is only 240 geographical miles."

NOTES.

THE Gilbert Club, to which we referred last week, was formally founded on Thursday, November 28. The following officers were appointed at the first general meeting:—President, Sir William Thomson. Vice-Presidents: Lord Rayleigh, Prof. D. E. Hughes, Prof. Reinold, Mr. Jonathan Hutchinson (President of the Royal College of Surgeons), Dr. B. W. Richardson, and Mr. H. Laver, of Colchester. Mr. Latimer Clark was elected Treasurer, and Mr. Conrad Cooke, Prof. R. Meldola, and Prof. S. P. Thompson, Hon. Secretaries. The resolution finally adopted by the meeting was:—"That the objects of the Gilbert Club be as follows:—(1) To produce and issue an English translation of 'De Magnete' in the manner of the folio edition of 1600. (2) To arrange hereafter for the tercentenary celebration of the publication of 'De Magnete' in the year 1900. (3) To promote inquiries into the personal history, life, works, and writings of Dr. Gilbert. (4) To have power, after the completion of the English edition of 'De Magnete,' to undertake the reproduction of other early works on electricity and magnetism, provided at such date a majority of the members of the Club so desire." At the time of the inaugural meeting eighty-seven members had joined the Club.

PROF. J. BRYCE's speech (read by Prof. Holland) at the presentation of Mr. A. R. Wallace for the degree of D.C.L., *honoris causâ*, at Oxford, on November 26, was one of unusual interest. We may note especially the very masterly way in which the doctrine of the survival of the fittest was expressed. After describing Mr. Wallace's travels in Brazilian forests, and among the islands, "quæ ultra Chersonesum aureum soli nimium propinque subjacent," the speech referred to his discovery of the theory according to which new species are evolved, which was shortly stated as, "ea corpora vigere magis prolemque ex iis lætiorem surgere quæ ipsa nescio quo pacto natura vitæ periculis subeundis aptissima creaverit: sic stirpem a cæteris stirpibus dissimilem et in dies longius discrepantem propagari." The contemporaneous discovery of natural selection by Charles Darwin, and his cordial recognition of Mr. Wallace's merits, were mentioned: "tanta et in hoc et in illo inerat animi nobilitas veritatis quam gloriæ propriæ studiosior." Reference was made to Mr. Wallace's various writings.

WE regret to announce the sudden death of Dr. W. R. McNab. He died at his residence in Dublin on Tuesday morning, the 3rd inst. Dr. McNab was Professor of Botany in the Royal College of Science, Dublin, having succeeded Prof. Thiselton Dyer, F.R.S. He was also Scientific Superintendent and Referee to the Royal Botanic Gardens, Glasnevin, under the Science and Art Department. He appears to have been in his usual health on Monday, and on St. Andrew's Day (Saturday) took an energetic part in the meeting and banquet held by the Scotch residents in Dublin.

THE *Colonies and India* reports the death, in Melbourne, of Mr. Robert Brough Smyth, who was for sixteen years Secretary of Mines in Victoria. He was well known in Australia for his contributions, especially on geological questions, to scientific literature.

THE new Natural Science Museum of Berlin was opened on Monday. The Berlin Correspondent of the *Standard*, describing the proceedings, says that the ceremony was striking. A handsome tent, surmounted by an imperial crown, was erected for the Emperor and Empress, who were present with the Princess Frederick Charles, Prince Alexander, the Hereditary Prince and Princess of Meiningen, and a brilliant suite. Nearly all the Ministers, including Count Bismarck, who has just returned from Friedrichsruh, and the Minister of War, were in attendance. Count Waldersee, representatives of the Academy of Art, and the Professors of the University, were also present. Dr. von Gossler, Minister of Education, delivered an eloquent address, in which he mentioned that the collections were founded a hundred years ago, and expressed the hope that both science and the State would derive equal benefit from the new institution. Prof. Beyrich, the first Curator of the Museum, pledged himself to keep abreast with the progress of science. Their Majesties were conducted through the building by the keepers of the various collections.

THE Paris Museum of Natural History is about to elect a successor to M. Chevreul in the Chair of Chemistry.

AT the general monthly meeting of the Royal Institution, on December 2, the managers reported that they had re-appointed Prof. James Dewar, F.R.S., as Fullerian Professor of Chemistry.

THE Academy of Sciences of Vienna has appointed Prof. G. Niemann, of Vienna, and Major Steffan, of Cassel, to be present as impartial witnesses at the excavations at Hissarlik, begun, on November 25, under the direction of Dr. H. Schliemann and Dr. W. Dörpfeld. Captain Ernst Bötticher, who has often called in question the utility of Dr. Schliemann's archæological investigations, has been requested to take part in the excavations.

MR. HUGH G. BARCLAY, in his Report as to the fund for the preservation of birds in the Farne Islands, says he has every reason to believe that the birds were very well protected this season. He visited the islands twice, and each time he satisfied himself, by his own personal investigations, that the birds had

not been unduly disturbed. Last year, at the request of the authorities, he allowed some young birds to be taken from the islands for the purpose of being placed on the lake at St. James's Park, London. The following is an extract from a letter he lately received from Mr. Rilly, the bird-keeper there :—"The only birds alive now of those brought from the Farne Islands are the cormorants, which are thriving. The puffins all died during the first three months. The guillemots lived somewhat longer, the death of the last one being the result of an accident. The one kittiwake also died by an accident. The terns died during the severe frost, being apparently unable to get about on the ice, their tail and wings collected the ice; I suppose on account of their being pinioned and not being able to use their wings freely."

THE Council of the Dundee and District Association for the Promotion of Technical and Commercial Education has issued its first Annual Report, and is able to give a very good account of the results it has achieved. With regard to the future work of the Association, the Council suggests that workshop instruction for lads engaged at unskilled work in factories and during the day should be established in connection with the evening classes of the School Board. It also proposes the drafting of additional courses of instruction, especially in painting, decoration, and pattern designing, and the encouraging of higher classes in these subjects. In this connection the Council appropriately refers to the fact that in 1884 the Technical Instruction Commissioners reported that "the crowded schools of drawing, modelling, carving, and painting, maintained at the expense of the municipalities of Paris, Lyons, Brussels, and other cities—absolutely gratuitous and open to all comers, well lighted, furnished with the best models, and under the care of teachers full of enthusiasm—stimulate those manufactures and crafts in which the fine arts play an important part to a degree which is without parallel in this country."

A SERIES of questions on the effects of London fogs on cultivated plants has been issued by the scientific committee of the Royal Horticultural Society. The experience of the current season only is to be utilized.

A SPECIMEN of the *Rorqual musculus* has just come ashore on the coast of the Médoc district. Dr. Beauregard, *aide naturaliste* at the Paris Museum, went to the spot to examine this interesting cetacean. Unfortunately, the brain was already in a state of decomposition, but the breasts and ears were dissected off for complete examination. The animal was 14 metres long, and 6 metres in circumference at the thickest part of the body.

PROF. CHAUVEAU has lately published in the *Archives de Pathologie Expérimentale* a contribution to the study of "transformism" in microbiology. His researches relate to *Bacillus anthracis*, and show that by experimental means various important biological alterations may be obtained.

PROF. MARSHALL WARD is about to deliver, at th eCity and Guilds of London Institute, a course of six lectures on timber, its nature, varieties, uses, and diseases. The lectures will be given on Monday and Thursday evenings, at 7.30 (December 12, 16, and 19, and January 23, 27, and 30). The object of the course is to explain as simply and clearly as possible, with the aid of numerous lantern illustrations, the nature, properties, varieties, and uses of the ordinary timbers used in construction, and to give an intelligible account of dry-rot, and allied diseases of timber.

THE second series of lectures given by the Sunday Lecture Society will begin on Sunday afternoon, December 8, in St. George's Hall, Langham Place, at 4 p.m., when Mr. W. Lant Carpenter, B.Sc., will lecture on "The Wonders of the Yellowstone Park—a Personal Narrative," with oxy-hydrogen lantern illustrations from the lecturer's own camera. Lectures will also be given by Commander V. L. Cameron, R.N., Mr. J. F. Blake, Mr. Henry Blackburn, Mr. Wilmott Dixon, Mr. Stanton Coit, and Mr. Eric S. Bruce.

THE annual general meeting of the Institution of Electrical Engineers will be held at the Institution of Civil Engineers, 25 Great George Street, Westminster, on Thursday, December 12, at 8 o'clock in the evening, for the reception of the annual report of the Council, and for the election of Council and Officers for the year 1890. The following paper will be further discussed: "Electric Engineering in America," by Mr. G. L. Addenbrooke.

IT is stated that a scheme is on foot for establishing a Natural History Society in the Punjaub. It is to be hoped that it will be successful, and that the Society will flourish as other Indian scientific societies are doing.

IN the introductory lecture to the agricultural class at the University of Edinburgh, delivered at the opening of the present session, Prof. Wallace chose as his subject some aspects of Australasian agriculture. In this lecture, which has now been printed, Prof. Wallace urges that sheep farmers in this country will shortly feel the effects of rivalry with the flock masters of Australia. There are 100,000,000 sheep in Australia, mostly merinos, which are not, by the way, a flesh-yielding but a wool-giving race. Prof. Wallace hazards the opinion, by a very easy process of arithmetic, that, before many years have passed, Australia will be possessed of over 200,000,000. He makes, also, the astonishing statement that merino mutton is equal in flavour and texture to our best Highland, Welsh, or South Down mutton. Upon these two assumptions, for they are nothing more, he foretells calamities to the meat producers of this country, which he, it is to be hoped, will not live to see.

A STALACTITE cave has been discovered in Ascheloh, near Halle, in Westphalia; it is reported to be more than 100 metres long.

A SHARP-shock of earthquake was felt at Oran, Algeria, on November 27, at 3 p.m. It lasted ten seconds, the oscillations being from east to west.

ACCORDING to a telegram sent through Reuter's agency from Belgrade on December 2, violent shocks of earthquake, accompanied by loud subterranean rumblings, were felt on Sunday afternoon at Kregugewatz, Jagodina, and Kupsia. The disturbance generally travelled from east to west, but some of the shocks moved from north to south.

MR. H. C. RUSSELL, Government Astronomer of New South Wales, has published the results of meteorological observations made in that colony during 1887. The number of reporting stations is now 862, being 94 more than in 1886, the increase being almost wholly in rain stations. The arrangement of the tables, which give the most important data for each station separately, is the same as in previous years; but there are also two new tables giving the mean maximum and minimum temperature at Sydney for each month from 1856 to 1887. The mean temperature of the whole colony for the last seventeen years is 61°·2. At Sydney the mean for thirty years is 62°·7. The diagrams appended to the volume give a good idea of the weather conditions at Sydney, and clearly exhibit the peculiarities of certain periods, such as the very short winter of 1873, and the long one of 1874, also the long summer of 1877–78, with four months of hot weather, and the short summer of 1886-87, when there was only one month of hot weather. In 1878 the lowest winter temperature occurred in June, and in 1872 in August. A comparison is made of the rainfall at the principal places in the various colonies. The contrast between the amount at Brisbane and Sydney and that at Melbourne is very striking. At the former places as much rain sometimes

falls in one month as would make a year's rainfall at Melbourne. At Sydney the least annual rainfall on record is 21·48 inches, and the greatest 82·81 inches. The question of evaporation continues to receive considerable attention; the tabular results are published, with the rain and river results, in a separate volume.

THE Meteorological Report of the Straits Settlements has been published for the year 1888, being the fifth year in which meteorological observations in the colony have been made the subject of a general systematic report. The temperature of the air ranged between 67°·2 and 96°, and solar radiation varied from 81° to 179°; the lowest temperature on the grass was 61°. Rainfall observations were received from forty-one stations. The annual amount differs considerably in the various provinces, the mean of the stations ranging from 65·6 inches in Singapore, to 111·7 inches in Penang, and 123·2 inches in Province Wellesley. The greatest fall in twenty-four hours, was 12 inches at Bertam, Province Wellesley, on October 21. The Report also contains a tabular statement of annual and monthly rainfall at Singapore since 1869, and diagrams of annual rainfall and other elements since 1870, at the same place.

THE International Commission for the scientific investigation of the Lake of Constance have nearly finished their task, which consisted of drawing a new and comprehensive map on a scale of 1 : 25,000; investigating the currents, density, temperatures, and chemical composition of the water; and minutely describing the flora and fauna of the lake. A full account will be issued when the researches are complete.

WE have received the latest instalment (pp. 321-84) of vol. xvi. of the Proceedings of the Royal Society of Edinburgh, session 1888-89. It contains:—The solubility of carbonate of lime in fresh and sea water, by W. S. Anderson, chemist at Marine Station, Granton (continued); secretion of carbonate of lime by animals, part ii., by Robert Irvine and D. G. Sims Woodhead; theoretical description of a new "azimuth diagram," by Captain Patrick Weir, communicated by Sir William Thomson; note on Captain Weir's paper, by Prof. Tait; on the coagulation of egg and serum albumen, vitellin, and serum globulin, by heat, by Dr. John Berry Haycraft and Dr. C. W. Duggan.

THE fourteenth part of Cassell's "New Popular Educator" has been published. It includes a clearly printed map of the world.

AT a recent meeting of the Bombay Anthropological Society, Mr. W. E. Sinclair, of the Civil Service, read a paper on flint remains in the Kolaba district. Referring to a collection belonging to the Society made in the Ghar Hills, near Sukker, on the Indus, Mr. Sinclair said that these hills were evidently a sort of "Black Country" to the flint-using races. Cones and flakes can be got there literally by the hundredweight. There is no historical evidence of the use of such things in India proper. On the contrary, all historical evidence points to the conclusion that India was one of the first countries to use iron, if not the very first. Amongst the wildest forest tribes to-day the use of stone does not go beyond weighting a fishing-line or bird arrow with a pebble; and although stone spindle-weights are still used on the coast, these are no more barbarous than the stones in an English mill. These cones of flint are covered with long grooves of a curved section; and the flakes show each one face corresponding to such a groove, which shows that they have been struck off such cones. The cones themselves have a peculiar typical form, and the art of producing flake or cone is one lost in the India of to-day. Where a flint shows that peculiar groove, there is good reason to assume that it was made before iron was known in India. On all the agates and chalcedonies in the Kolaba collection there are the same strange grooves, the same long blade-like flakes matching them, as in Sind or in England or France; and we are, in fact, in presence of a lost art, for which there has been no occasion from the time that iron came into common use. That was a long time ago in India. Steel—and very good steel, too—must have been for many generations in the hands of the ancient inhabitants of the Konkan when the first cave temples were hewn—at least 2000 years ago. On the other hand, the position of the flakes, both in Sind and in Kolaba, shows that they belong to a very recent geological period. The Kolaba specimens, except one or two, come from the surface of the lacustrine gravels abundant in the valleys of the Konkan. All search for them in places where sections of these gravels are exposed has hitherto been fruitless, and the few water-worn specimens found came out of a river bed. They most commonly occur at places where fresh water is to be had near an estuary.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Colonel J. D. C. Ferrell; two Common Marmosets (*Hapale jacchus*) from South-East Brazil, presented by Mr. Charles Petrzywaski; an Arctic Fox (*Canis lagopus* ♀) from Siberia, presented by Mr. Stuart N. Corlett; a Corn Crake (*Crex pratensis*) from Essex, presented by Mr. Bibby; four Common Snakes (*Tropidonotus natrix*), British, presented by the London, Chatham, and Dover Railway; a European Bison (*Bison bonasus* ♂) from Central Europe, deposited; a Stanleyan Chevrotain (*Tragulus stanleyanus*) from Ceylon, a Prevost's Squirrel (*Sciurus prevosti* ♂) from Malacca, a Common Roe (*Capreolus capræa* ♂), European, a White-faced Tree Duck (*Dendrocygna viduata*) from Brazil, four Black-necked Swans (*Cygnus nigricollis*) from Antarctic America, a Curlew (*Numenius arquata*), British, two Indian Cobras (*Naia tripudians*) from India, an Annulated Snake (*Leptodira annulata*) from Panama, a Hawk's-billed Turtle (*Chelone imbricata*) from the East Indies, purchased; two Crested Pigeons (*Ocyphaps lophotes*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m., December 5 = 2h. 59m. 33s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.

Remarks.

(1) The General Catalogue description of this nebula is as follows:—Pretty bright, pretty small, round, brighter in the middle. The spectrum has not yet been recorded.

(2) This is a star of Group II., in which Dunér records the bands 2-8, and states that the bands 2 and 3 are especially well developed. This latter fact indicates that the star is well advanced, and it accordingly falls in a late species (13) of the group. As I have before pointed out with reference to similar stars, absorption *lines* of metallic substances, and possibly of hydrogen, may be expected at this stage, and it is important to note the presence or absence of these, as they will probably form a connecting link between the stars of this group and the slightly hotter stars of Group III. The intensity of the bright carbon fluting near *b*, as compared with its appearance in other stars of the group, will be an additional check in placing it in position on the "temperature curve."

(3) This is classed with stars of the solar type by Gothard, but there is not sufficient detail in his description of the spectrum to enable us to say whether it be Group III. or V. Further observations with special reference to this point are therefore required (for criteria, see p. 20). Gothard's statement as to the colour of the star should be checked, as most of the stars of Groups III. and V. are yellowish. The stars which are not far removed from Group IV., on either side, are the whitest.

(4) This is a star of Group IV., and the usual observations are suggested.

(5) This is a very fine example of the stars of Group VI., showing the subsidiary bands 4 and 5. The band 6 (λ 564) appears to be most subject to variation in the different stars of the group as described by Dunér, in some cases being wide and pale, and in others wide and dark. As this may subsequently form the basis of a temperature classification, the character of the band in the star under consideration should be carefully noted. The presence or absence of lines in the spectrum should also be recorded. [Dunér's notation for the bands in the spectrum of stars of Group VI. is as follows:—(1) 656, (2) 621, (3) 604·8, (4) 589·8, (5) 576·0, (6) 563·3, (7) 551, (8) 528·3, (9) 516·3, (10) 472·7. (6), (9), and (10) are the dark flutings of carbon.]

(6) The period of this variable is given by Gore as 210 days, and the magnitudes at maximum and minimum as 7·7–9·2 and 12·5 respectively. The spectrum has not yet been recorded. The maximum will occur on December 15.

(7) This variable has a period of 288·1 days, the next maximum occurring on December 14. The magnitude at maximum is given by Gore as 8·1–8·7, and that at minimum as < 13. It is still doubtful whether the star belongs to Group II. or to Group VI., and the approaching maximum may afford an opportunity of settling the question.

A. FOWLER.

SUN-SPOT OF JUNE, JULY, AND AUGUST, 1889.—The Memoir of the Società degli Spettroscopisti Italiani for October contains a series of observations by Prof. Riccò of this spot. The latitude of the spot from its appearance on June 16 and during the first semi-rotation, varied between the limits $-5^\circ\!\cdot\!9$ and $-7^\circ\!\cdot\!5$. At the second appearance, the variation was between $-7^\circ\!\cdot\!5$ and $-10^\circ\!\cdot\!8$, whilst at the third appearance, in August, the limiting latitudes were $-8^\circ\!\cdot\!5$ and -10°.

The group of spots that appeared on June 30 was found to have a latitude as high as -41°. The following day, however, the latitude was found to be $-40\frac{1}{2}^\circ$, and on July 2 the group disappeared.

Prof. Spörer, in a communication to Prof. Riccò, notes that the following bright lines were measured at Potsdam on June 28 in a prominence that appeared as the above large spot was disappearing over the sun's edge.

PHOTOGRAPHIC STAR SPECTRA.—As a portion of the Henry Draper memorial, the spectra of stars are being photographed at Chosica in Peru. Of the photographs that have been received at Harvard College, Prof. Pickering notes (*Astr. Nachr.*, No. 2934) several have similar spectra to the "bright line" stars in Cygnus. The hydrogen line F is bright in θ Muscæ, the same as in γ Cassiopeiæ, and the presence of bright hydrogen lines in η Argûs and R Hydræ is also confirmed by the photographs.

Numerous photographs have been taken at Harvard College of the spectra of the stars in the Pleiades, and an examination of them shows that the hydrogen line F in the spectrum of Pleione D.M. + 23° 558, consists of a narrow bright line superposed on a broader dark line. The other hydrogen lines, especially that near G, show some indications of a similar effect.

With respect to this, Prof. Pickering observes that an interesting analogy between the Pleiades and θ Orionis appears in the fact that in both cases extensive nebulosities surround stars with bright lines in their spectra.

COMET BROOKS (*d* 1889, JULY 6).—The following elements and ephemeris have been computed by Dr. Knopf from observations made at Mount Hamilton, July 8; Dresden, August 25; and Vienna, October 24:—

T = September 29·7436 Berlin Mean Time.

$$\left.\begin{aligned} \omega &= 343^\circ\ 18'\ 56''\!\cdot\!5 \\ \Omega &= 17\ \ 58\ \ 29\cdot6 \\ \iota &= 6\ \ \ 3\ \ 59\cdot6 \end{aligned}\right\}\ \text{Mean Eq. } 1889\cdot0.$$

$$\begin{aligned} \phi &= 28\ \ 4\ \ 13\cdot3 \\ \mu &= 501''\!\cdot\!8156 \\ U &= 7\cdot071 \text{ years.} \end{aligned}$$

Ephemeris for Berlin Midnight.

Mr. Chandler notes (*Astr. Jour.* No. 204) that the result of an inquiry into the corrected elements of this comet is extremely interesting. The descending node of the comet's orbit upon that of Jupiter lies at 185°·5 long., Jupiter's aphelion at 191°, and the comet's aphelion at 183°. The aphelion distances are 5·4541 and 5·3992 respectively, the mutual inclination of the orbits is 3°, and the orbital velocities nearly the same; so that when both bodies happen to be near this region they will remain together many months.

COMET SWIFT (*f* 1889, NOVEMBER 17).—The following elements and ephemeris are given by Dr. Zelbr in Circular No. 69, issued by the Vienna Academy of Sciences, November 25, 1889, and have been computed from observations made at Rochester, November 17; Vienna and Palermo, November 20; and at Vienna, November 22:—

T = 1889 December 10·5665 Berlin Mean Time.

$$\left.\begin{aligned} \Omega &= 309^\circ\ 51'\ 12'' \\ \omega &= 109\ \ 24\ \ 70 \\ \iota &= 7\ \ 14\ \ 1 \end{aligned}\right\}\ \text{Mean Eq. } 1889\cdot0.$$

$$\log q = 0\cdot07554.$$

$$\Delta\lambda \cos\beta = +132'' \ \ldots\ \Delta\beta = -14''.$$

Ephemeris for Berlin midnight.

1889.	R.A. h. m. s.	Decl. ° ′	Log Δ.	Log r.	Brightness.

The brightness at discovery has been taken as unity.

S CASSIOPEIÆ.—The Rev. T. E. Espin, examining the spectrum of this star on November 27, found that it resembled in appearance that of R Andromedæ, the bright F line blazing out upon the background of the continuous spectrum, and being plainly visible even with the least dispersion used. The star is not included by Dunér in his classical work, "Les Étoiles à Spectres de la Troisième Classe," but its general spectrum is apparently of that type—Group II. of Mr. Lockyer's classification. Mr. Espin adds that "the yellow is brilliant, suggesting (bright) lines, but the star is at present too faint to be sure."

The star is a variable of very long period, 607·5 days; the next expected maximum falls on December 26, so that it may show some further and interesting developments during the next three weeks. Chandler, however, records his suspicion that the period is shortening, so that the actual maximum may be very close at hand. The maximum brightness varies from 6·7 mag. to 8·6. Mr. Espin estimated it as 7·8 on the night of observation. Place for 1890: R.A. 1h. 11m. 34s.; Decl. 72° 1′·9 N.

THE ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

ON Saturday last, St. Andrew's Day, the Royal Society held its anniversary meeting. The President read the anniversary address, a copy of which has not yet reached us. The medals were then presented as follows: the Copley Medal to the Rev. Dr. Salmon (received by Sir R. S. Ball); the Davy Medal to Dr. Perkin; a Royal Medal to Dr. Gaskell; and a Royal Medal to Prof. Thorpe. The Society next proceeded to elect the Officers and Council for the ensuing year. The selected names we have already published.

In the evening the Fellows and their friends dined together at the Whitehall Rooms, Hôtel Métropole, the President in the chair. Over two hundred Fellows and guests were present.

The toast of "The Royal Society" was proposed by the Speaker of the House of Commons. He said:—Sir George Stokes and Gentlemen,—If I thought the audience whom I have the honour to address, took the same view as I do of my own want of qualifications for proposing this toast, I think I should at once sit down; but it is because I trust to your generous forbearance for a few moments that I ask you to allow me to propose a toast which needs no advocacy of mine, the toast of the Royal Society. I suppose the reason why your President has selected me to propose this toast is owing to the fact of the official position that I hold in the House of Commons, and also partly owing to the fact that the holder of one chair has been willing to pay a compliment to the holder of another. There are very few members of the House of Commons, I believe, who are entitled to put three letters to their name to indicate membership of your Society. I omit those Privy Councillors who, I believe, by virtue of their office, have a claim to be looked upon as members of this Society. I am speaking now of the strictly scientific men, and I believe I could number the strictly scientific members of the House of Commons who are members of the Royal Society on the fingers of one hand. But I may say that those members of the House of Commons make up for their numerical weakness by the qualities they display, the high place they have filled, by their pre-eminence in debate, and by the records they have left upon the Statute-book of the country. It may be said that five members is a small infusion to leaven the whole lump of the House of Commons, and I am very conscious that scientific gentlemen may regard at times with a feeling of displeasure, if not with a more contemptuous feeling, some of our modes of procedure and some of our habits of thought in the House of Commons. You may think that we do not display that calmness of judgment, that patient investigation of detail, which characterize the scientific mind: You may think that we import into our discussions too much of a very unscientific heat, and that we are diverted from our objects by a great many cross-currents of prejudice and of party. However that may be, Sir, I believe that the object that you and we have in view is the same. The great historian Hume, speaking of the inception of this Society, said that it was the part of scientific men to lift the veil from the mysteries of Nature. It is a humbler function which the House of Commons has to discharge—to solve the great social and political questions of the day. But the object of both is the same, the attainment of truth, and, by whatever means we can attain that object, that object ought to be the main purpose of our lives. I believe I am right in saying this Society owes its inception and its origin to the University of Oxford. In these later days it owes a debt to the great sister University, in the fact that that University has sent to the chair of your Society a gentleman who combines in his own person, not for the first time, the functions of a Professor, of a member of the University of Cambridge, and of President of this great scientific body. Sir, I am very loth, indeed, to trespass any longer upon your time. I have no claim whatever to do so. I will only very humbly express my views. My own individual opinion is worthless and insignificant; but possibly invested for a few moments with a representative character, and speaking for the House of Commons, and that great public who are behind it, I would say that the public of the present day regard not only with that vague astonishment, which they might well do, the great achievements of science, but they look with admiration upon the great men who have illustrated the history of your Society, and they see in that very lengthened list one of the greatest tributes to the greatness of their country. I do, Sir, very much feel the imperfection with which I have addressed to you these few words. But if I have said that the scientific mind is needed in the House of Commons, I will also say this, that the House of Commons has in these days to face not only great political problems, but some of those questions which are surging up and coming ever more to the front, I mean the great social problems—problems connected with the aggregation of vast multitudes in towns, problems connected with the question how to make the lot of the poor happier, how to make it easier for men to support a life of continuous labour, how, in short, to sweeten life, and to make that toil which falls upon us all lighter to the poor with some ray of hope, and easier with some degree of comfort and convenience. But it is to science that the public must look for aid in solving these questions. You have done much already, but you will add a still nobler title to the admiration of the world if you deal with these subjects, as I am sure you will, in such a manner as to make it impossible for the practical politician to separate himself from the nobler follower of science. It is with a very deep sense of the value of this Society and of the feeling which is abroad with regard to it, that I beg to propose to you—and I thank you most cordially for the toleration with which you have listened to my few remarks—the toast of "The Royal Society."

In response, the President said:—My Lords and Gentlemen,—On behalf of the Society which I have the honour to represent on this occasion, I beg to return our thanks for the honour you have done us in drinking the toast. This Society is by far the oldest scientific Society in the Kingdom, but it cannot for a moment compare in antiquity with that other institution over which the Speaker presides. Our aims are of course naturally very different, and our modes of procedure are different too. We have, as the other House has, discussions in our body, but our discussions are usually carried on with calmness, and we endeavour—those of us who pursue different branches of science—to assist one another. I do not think that that is always the case in the other Society. Perhaps there is nowadays at times something akin to obstruction rather than assistance. However, in order that truth may be elicited, it is necessary that there should be contact between mind and mind, and contact sometimes produces severance. It is better that that contact should take place in order that we should understand one another. Our Society does not exactly deal with social problems such as the Speaker has alluded to, still there are many cases in which questions of great interest to the bulk of the population are capable of being illuminated by scientific researches. To take one remarkable example which has been brought prominently before us. Let us consider the investigations, so important in their results, so purely scientific in inception, which have been carried on by M. Pasteur in France. As the result of a long series of scientific experiments, he has now succeeded in protecting in a great majority of instances those persons who have been so unfortunate as to have been bitten by rabid animals from that terrible disease which ordinarily follows in the wake. His merits in that respect have been duly acknowledged in this country. We know that recently, within the course of the present year, the Lord Mayor called a meeting at the Mansion House to make some recognition on the part of this country of the great debt which we owe to M. Pasteur for those researches. I mention that as one, but it is only one, of many instances in which great social advantages have accrued from purely scientific investigation. I trust that harmony will long continue to exist between the Society which I have the honour to represent, and that which the Speaker represents. I can say this much—that, whatever Government may have been in power, there have frequently been applications made to the Royal Society for advice on some purely scientific questions on which the Cabinet of the day did not feel that they had the requisite knowledge to pronounce an opinion; and this I must say, that the Royal Society has freely given the best of their knowledge on these subjects to the Government of the day, without any consideration of what the politics of that Government might be. I trust that this will ever continue to be the case, and that the Royal Society may go on in a peaceful way doing the duties which belong to it, and that the country may reap the benefits resulting therefrom.

Responding for the toast of "The Medallists," proposed by the President, Prof. Thorpe said:—Mr. President, my Lords, and Gentlemen,—We must all regret, I am sure, that Dr. Salmon's duties as Provost of Trinity College, Dublin, should have prevented him from being present amongst us to-day to receive the Copley Medal in person and to respond to the toas

which has just been so cordially drunk by you. For reasons which my brother medallists at least can fully appreciate, no one feels that regret more keenly than I do. I may confess that it was with a feeling akin to astonishment that I received through a good-natured friend the intimation that the Council of the Society had seen fit to honour such chemical work as I had been able to do by the signal recommendation of the award of a Royal Medal; but that feeling culminated into something like consternation when you, Sir, informed me of your wish that I should reply, in the absence of the Copley Medallist, to the toast with which you have connected my name; and I began to realize the full force of the truth that there are occasions when it is more blessed to give than to receive. Dr. Salmon's absence, however, enables me to attempt to give expression to the feeling of satisfaction and pleasure with which, I am informed, the mathematical world regards this year's award of the Copley Medal. The worker in the field of pure mathematics appeals for recognition to a very select few; his work is, indeed, *caviare* to the general; his are not the triumphs which appeal to the popular fancy or which strike the popular imagination. If he labours for fame, he must be content to wait with the certain knowledge that, if his work be good and true, it will at length meet with the recognition it merits from a tribunal which is unmoved by prejudice and is insensible to the forces of fashion or faction. For nearly half a century Dr. Salmon has so worked, and to-day he receives his reward at the hands of the highest scientific tribunal in the world by the award to him of the most precious gift which it is in the power of that tribunal to bestow. The other medallists, Dr. Gaskell and Dr. Perkin, are happily with us to-night to receive the congratulations of their fellow-workers in science, and to be witnesses of the cordiality with which their health has been drunk by you. But I cannot forego the opportunity of saying also, in their case, how entirely your awards have been appreciated by the great body of scientific opinion, both within and without the Royal Society. To be praised by men who are themselves praised is, we all know, the very highest form of approbation that a man can enjoy, and such, to my knowledge, is the happy lot of the gentlemen whom you have been pleased to honour to-night. It is, however, one of the penalties to a man who is in the position in which I now find myself, and who does not pretend to be an Admirable Crichton, that he is unable from his own knowledge, or rather from the imperfection of it, to do adequate justice to the claims which such men have upon your regard. Dr. Gaskell's work is so entirely outside my own province that it would be in the highest degree presumptuous on my part to offer you any expression of my own opinion as to its merits. Of my colleague and fellow-worker, Dr. Perkin, to whom your Council has awarded the Davy Medal, I trust I may be allowed to speak with greater freedom, because in his case I am more or less upon my own ground, and am talking about matters which are within my own knowledge. It is exactly ten years since that Dr. Perkin was placed by your Council in the position in which I find myself to-day. In awarding him a Royal Medal on that occasion, our former President, the late Mr. Spottiswoode, took the opportunity to say that Dr. Perkin had then been, during more than twenty years, one of the most industrious and successful workers in organic chemistry, and he added that it was seldom that an investigator had extended his researches over so wide a range as was the case with Dr. Perkin, whose work had always commanded the admiration of chemists for its accuracy and completeness, and for the originality of its conception. There is not a chemist here present who will not cordially re-echo these words. Dr. Perkin is, no doubt, known to you all as the originator of one of the most important branches of modern chemical industry—that of the manufacture of colouring matters from coal-tar derivatives—an industry which has acquired almost colossal proportions, and which has effected a complete revolution in the tinctorial arts. I say it with bated breath to you, Sir, as the member for the University of Cambridge, but we all remember the famous saying of Swift as to the value to mankind of the whole race of politicians put together when compared with that man who has made two blades of grass to grow where only one blade grew before. I do not know that Dr. Perkin has achieved that feat, but I claim for him that he has done even more than this, for he has succeeded in demolishing an entire agricultural industry. By his researches he has shown us that we have practically at our own doors, or at least in our own coal-pits, all the richness and beauty of colour which were formerly only to be obtained from the madder fields of Avignon and the Levant. A beneficent fortune, we are glad to know, has not been unmindful of Dr. Perkin's success in thus enriching the world, and she has endowed him with a share of that material benefit which his skill and genius as an investigator has conferred upon us all. That competency, and the well-earned leisure which has sprung from it, Dr. Perkin has dedicated, with a directness and singleness of purpose which merits our warmest appreciation, to the service of science. Nothing, I think, more clearly indicates the truly scientific character of his mind, and his love of science for its own sake, than that he should, whilst comparatively a young man, have turned aside from the pursuit of the great wealth which all his friends thought would ultimately be within his grasp in order that he might follow, undisturbed, his innate desire for pure scientific research. The ten years which have elapsed since our late President alluded in such characteristically graceful terms to Dr. Perkin's labours in the domains of pure and applied chemistry have been rich in scientific achievement, and they have now culminated in that laborious series of researches on one of the most abstruse points of physical chemistry which has been so fittingly rewarded by you by the gift of the Davy medal. I have already alluded to the feeling with which I received the intimation from my good-natured friend that the Council of the Royal Society had been pleased to confer upon me a distinction which is my sole excuse for trespassing upon your indulgence to-night. I will only again refer to that feeling to say that in deference to the express wish of my distinguished friend I am doing my best to get over it. I am bound to add that my friend has himself supplied a reason which in some measure serves to explain the circumstance. Among the pieces of work which the Council have thought worthy of notice was a redetermination of the atomic weight of gold made in conjunction with Mr. Arthur Laurie. I shall not trouble you with the reasons which made that redetermination seem specially desirable, but that it was desirable will be evident from the fact that no fewer than three independent investigations were in progress at the same time in Germany, England, and America. All the results have now been published, and they are, I think, in very fair accord. But my distinguished friend, whose good-nature is only equalled by his candour, has reminded me that there is a discrepancy of a remote decimal place or so in our several values for the atomic weight, and, in default of any other probable hypothesis, it had occurred to him that the real motive of the Council in making the award was to give me both the hint and the opportunity to clear up the disparity. The Gold Medal, he pointed out, would afford an ample supply of the material on which to base a new determination, and the Silver Medal would come in handy for the preparation of the necessary standard solutions. This seemed to me to put the whole matter in a new light, but, on turning to the official intimation of the award forwarded to me by Dr. Foster, and then to a friendly letter which the President has been so good as to send me, I have not gathered that this intention was ever in the mind of the Council, and until I receive a further official intimation that such was the case, I mean to do my best to preserve intact the counterfeit presentment of the gracious lady which adorns the medals. There is just one other matter connected with my work to which, with your permission, I would allude. Reference was made in the terms of the award to a series of researches on fluorine compounds on which I have been engaged for some years past. I wish to mention, and I do so with a very special pleasure, that much of this work has been carried out in co-operation with some of my senior students at the Normal School of Science. This work has been at all times difficult, often disagreeable, and occasionally dangerous, and I am glad to seize this opportunity of testifying to the zeal, assiduity, and, I may add, courage, which my *collaborateurs* have shown in the progress of the investigations. It is a further satisfaction to me to add that the qualities thus evoked and the training thus acquired have been of material benefit to them in their professional advancement, and I can wish them no greater good fortune than that it may be their lot in time to come to occupy my place here, and to be received by you with that indulgence which you have extended to me to-night.

A NEW METHOD OF PREPARING FLUORINE

A NEW method of preparing fluorine has been discovered by M. Moissan. This discovery is the outcome of the success which has attended M. Moissan's efforts to prepare anhydrous fluoride

of platinum. During the process of his memorable work upon the isolation of fluorine by the electrolysis of hydrofluoric acid containing hydrogen potassium fluoride, one of the most remarkable phenomena noticed was the rapidity with which the platinum rod forming the positive electrode was corroded by the action of the liberated gaseous fluorine. It was surmised that a fluoride of platinum was the product of this action, but hitherto all efforts to isolate such a body have proved unsuccessful. In fact, for a reason which will be discussed subsequently, it is impossible to prepare platinum fluoride in the wet way. M. Moissan has, however, been enabled to prepare anhydrous platinum fluoride by the action of pure dry fluorine itself upon the metal. It was found at the outset that, when fluorine is free from admixed vapour of hydrofluoric acid, it exerts no action whatever upon platinum, even when the latter is in a finely-divided state, and heated to 100° C. But when the temperature of the metal is raised to between 500° and 600° C., combination readily occurs with formation of tetrafluoride of platinum and a small quantity of protofluoride. The moment the gas is mixed with a little vapour of hydrofluoric acid, the action is immensely accelerated, and then occurs readily at ordinary temperatures. The same rapid action occurs when platinum is placed in hydrofluoric acid saturated with free fluorine, which accounts for the disappearance of the positive terminal during the electrolysis. In order to prepare the fluoride of platinum, a bundle of wires of the metal is introduced into a thick platinum or fluor-spar tube, through which a current of fluorine gas from the electrolysis apparatus is passed. On heating the tube to low redness, the wires become rapidly converted to fluoride, when they are quickly transferred to a dry stoppered bottle. If the operation is performed in a platinum tube, a large quantity of fused fluoride remains in the tube. The tetrafluoride of platinum, PtF_4, formed upon the wires, consists either of fused masses of a deep red colour, or of small buff-coloured crystals resembling anhydrous platinum chloride. It is exceedingly hygroscopic. With water it behaves in a most curious manner. With a small quantity of water it produces a fawn-coloured solution, which almost immediately becomes warm, and decomposes with precipitation of hydrated platinic oxide and free hydrofluoric acid. If the quantity of water is greater and the temperature low, the fawn-coloured solution may be preserved for a few minutes, at the expiration of which, or immediately on boiling the solution, the fluoride decomposes in the manner above indicated. This peculiar behaviour with water explains the impossibility of preparing the fluoride in the wet way. When the anhydrous fluoride is heated to bright redness in a platinum tube closed at one end, fluorine at once begins to be evolved as gas, and if a crystal of silicon be held at the mouth of the tube it takes fire and burns brilliantly in the gas. The residual platinum is found on examining the contents of the tube to consist of distinct crystals of the metal. Hence by far the most convenient method of preparing fluorine for lecture purposes is to form a considerable quantity of the fluoride first by passing the product of the electrolysis over bundles of platinum wire heated to low redness, and afterwards to heat the fluoride thus obtained to full redness in a platinum tube closed at one end. It only remains now to discover another method of preparing fluoride of platinum in the dry way, to be able to dispense with the expensive electrolysis apparatus altogether. M. Moissan has also prepared a fluoride of gold in the same manner. It is likewise very hygroscopic, decomposable by water, and yields gaseous fluorine on heating to redness.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 21.—"On the Local Paralysis of Peripheral Ganglia, and on the Connection of Different Classes of Nerve-Fibres with them." By J. N. Langley, F.R.S., Fellow of Trinity College, and W. Lee Dickinson, Caius College, Cambridge.

We found that in the rabbit, 30 to 40 milligrams of nicotin injected into a vein stopped the effect of stimulating the sympathetic in the neck, not only on the pupil, but also on the vessels of the ear. It occurred to us that this action of nicotin might be due to a paralysis of the nerve-cells of the superior cervical ganglion, and not to a paralysis of the peripheral endings of the sympathetic nerve. On testing this view, we found that, after a certain dose of nicotin, stimulation of the sympathetic fibres below the ganglion does not produce dilation of the pupil or constriction of the vessels of the ear, whilst stimulation of the sympathetic nerve-fibres above the ganglion produces these changes in the normal manner.

The method of action of nicotin can be tested in a more direct manner by local application to the isolated nerve and ganglion. When the sympathetic in the neck has been brushed over with a 1 per cent. solution of nicotin, stimulation of it produces the usual dilation of the pupil and constriction of the vessels of the ear; but when the superior cervical ganglion and the filaments proceeding from it have been brushed over with the 1 per cent. nicotin, stimulation of the sympathetic in the neck is found to be completely without effect, while stimulation of the filaments running from the ganglion to the carotid arteries produces the normal action.

Hence nicotin paralyzes the cells of the superior cervical ganglion.

On the fibres of the cervical sympathetic, which are vaso-motor for the head generally and secretory for the salivary glands, we have made a few experiments only; but so far we have been unable to detect any effect from stimulating the sympathetic in the neck after nicotin has been applied to the ganglion.

We conclude that *the dilator fibres for the pupil, the vaso-constrictor fibres for the ear (probably also those for the head generally), and the secretory fibres for the glands, end in the cells of the superior cervical ganglion.*

Ganglion of the Solar Plexus.—In the dog, cat, and rabbit, the splanchnic nerve on the left side runs to two chief ganglionic masses, which we may call respectively the cœliac and superior mesenteric ganglia. The renal ganglia are scattered, but in the dog the chief one often lies underneath the supra-renal body, and in the cat the chief one is placed between the artery and vein about ½ inch from the superior mesenteric ganglion.

To determine whether the inhibitory fibres of the splanchnic end in the nerve-cells of the solar plexus we proceeded as in the case of the superior cervical ganglion. Having ascertained that the application of 1 per cent nicotin to the splanchnic leaves its inhibitory power unaffected, we found that nicotin applied to the whole plexus at once abolishes the inhibitory power of the splanchnic; but inhibition can still be produced by stimulating the fibres proceeding from the ganglia. Hence, *the inhibitory fibres of the splanchnic end in the cells of the solar plexus.*

Our experiments are not sufficiently numerous, especially with regard to the connection of the cœliac ganglion with the stomach, to make it certain that the one ganglion is entirely connected with fibres to the intestine, and the other with the fibres to the stomach; but we think they show *that in the main, and possibly altogether, the stomachic inhibitory fibres of the splanchnic nerve end in the cells of the cœliac ganglion, and the intestinal inhibitory fibres of the splanchnic end in the cells of the superior mesenteric ganglion.*

We find, however, that *the motor fibres of the vagus for the stomach and intestines do not end in the nerve-cells of the solar plexus.*

The connection of the vaso-motor fibres of the splanchnic with the nerve-cells of the solar plexus can be determined by taking a tracing of the arterial blood-pressure and stimulating the splanchnic before and after the application of nicotin to the ganglia. By applying nicotin to both ganglia, the rise of blood-pressure caused by stimulating the splanchnic is reduced to very small limits, and by applying it to the renal plexus as well, the effect of splanchnic stimulation on the blood-pressure is abolished. Since in this case there is no fall of blood-pressure, we conclude *that the vaso-dilator as well as the vaso-constrictor fibres of the splanchnic end in the cells of the solar and renal plexuses.*

Combining oncometer observations on the dog with blood-pressure observations on the rabbit and cat, we think there is fair evidence *that the splanchnic vaso-motor fibres for the kidney end in the cells of the renal plexus.*

We have experimented upon various peripheral ganglia other than those mentioned above, and, though our results are as yet incomplete, with essentially similar results; that is, we have obtained an abolition of the effect of some one or more of the classes of nerve-fibres running to them. We think, then, there is fair ground to conclude that *by stimulating the nerve-fibres running to and those from any peripheral ganglion, before and after the application of dilute nicotin to it, the class of nerve-fibres which end in the nerve-cells of the ganglion can be distinguished from those which run through the ganglion without being connected with nerve-cells.*

Linnean Society, November 7.—Mr. W. Carruthers, F.R.S., President, in the chair.—Mr. H. Veitch and Rev. Prof. Henslow exhibited a beautiful series of East Indian hybrid rhododendrons, on which Prof. Henslow made some valuable remarks on the effects of cross-fertilization in regard to colour and alteration of structure, upon which some critical observations were made by Mr. Veitch, Prof. Bower, and Captain Elwes.—Mr. E. M. Holmes exhibited and made remarks upon some new British marine Algæ, describing their origin and affinities.—Dr. St. George Mivart, F.R.S., exhibited a drawing by a surgeon, who had been consulted as to amputation of a tail-like process in the human subject, being a prolongation of the coccyx to the extent of 4½ centimetres. Dr. Mivart also exhibited a photograph, showing a remarkable resemblance between two arm stumps; one the result of an amputation, the other a congenital defect in the child of a nurse who had attended the patient whose arm was amputated. Both cases were commented on and explained by Dr. W. O. Priestley, and further remarks were offered by Dr. Murie, and Mr. W. Thiselton-Dyer.—Mr. W. B. Hemsley then read a paper by General Collett, C.B., and himself, on a collection of plants made in the Shan States, Upper Burmah. An interesting discussion followed, in which Messrs. J. G. Baker, C. B. Clarke, and Captain Elwes took part.

Anthropological Institute, November 12.—Dr. J. Beddoe, F.R.S., President, in the chair.—Dr. Beddoe read a paper on the natural colour of the skin in certain Oriental races. Dr. Beddoe's observations showed that the parts of the skin covered by clothing were very much lighter than those exposed to the sun and air; and that those people whose skin was the darkest in the covered parts, were not those who tanned to the blackest hue.—A paper by the Rev. James Macdonald was read on the manners, customs, superstitions, and religions of South African tribes.

PARIS.

Academy of Sciences, November 25.—M. Hermite in the chair.—On the November number of the *American Meteorological Journal*, by M. H. Faye. With this number begins the publication of a complete exposition of the author's theory of cyclonic movements, translated into English by Mrs. W. Harrington. The first part deals with storms, the second with tornadoes, while the third is occupied with the relations of tornadoes and storm phenomena to cyclones properly so called.—On animal heat, by M. Berthelot. In continuation of his previous paper on this subject, the author here discusses the question of the heat liberated by the action of oxygen on the blood. The quantity thus set free, referred to the molecular weight of oxygen (O_2 = 32 gr.), is found, by the extremely delicate experiments here described, to average 14·77 calories.—On the exhaustion of soils cultivated without manure, and on the value of the organic matter in the soil, by M. P. P. Dehérain. A series of experiments carried out at the Agricultural School of Grignon clearly shows that the substance chiefly lost by continuous cultivation without manure is carbon, the proportion of phosphoric acid, potash, and nitrogen eliminated being comparatively slight. It also appears that the organic matter itself is as important a fertilizing element for beetroot as are the nitrates, phosphates, or potash.—On the freno-secretory fibres, by M. Arloing. Experiments are described which demonstrate the existence of these fibres in the cervical chord of the large sympathetic nerve.—Observations on Swift's new comet (November 17) made at the Paris Observatory with the equatorial of the west tower, by M. G. Bigourdan. On November 21 the comet had the appearance of a very faint nebulosity (about 13·4), nearly round, diameter about 50″, without marked condensation. Observations made by Mdlle. D. Klumpke with the equatorial of the east tower on November 23 yielded similar results.—Generalization of Makeham's law of probabilities, by M. A. Quiquet. The chief property of Gompertz's formula as generalized by Makeham has been demonstrated in a very simple way by M. J. Bertrand. M. Quiquet in his turn now inquires whether this property may not itself be a particular case of a still more general principle, and whether the function discovered by the two eminent English actuaries may not therefore be capable of further generalization.—On the employment of electric conducting mediums in studying the displacements and distribution of acids with complex nature, by M. Daniel Berthelot. Of the numerous substances acting both as acid and as alkali one of the simplest is aspartic acid. The author here studies the equilibria that are produced in the presence of this acid in diluted saline solutions. The measurements have been made with the Lippmann capillary electrometer, by M. Bouty's electrometric method.—Variations of the electric resistance of nitric peroxide at different temperatures, by M. J. J. Boguski. Measurements obtained by several methods lead to the conclusion that an increase of temperature of nitric peroxide produces an increase of its electric resistance, the most abrupt variations occurring between 0° and 17° C. Above 70° this acid forms an almost perfect insulator. During the process of heating two consecutive phenomena were observed which call for special attention. To a rise of temperature up to a given limit generally corresponds a *static* and definite increase of resistance; but this increase itself *is preceded by a dynamic* (passing) *decrease* of resistance, whose momentary value is at times no more than $\frac{1}{100}$ or $\frac{1}{2000}$ of the static and normal resistance.—Preparation and properties of the anhydrous platinous fluoride, by M. H. Moissan. In continuation of his previous researches, the author here shows that platinous fluoride, $PtFl_2$, decomposes water at the ordinary temperature, which accounts for the impossibility of preparing it by the wet process. At red heat it is decomposed into crystallized platinum and fluorine.—Contribution to the study of double decompositions between the halogen salts of mercury and zinc, by M. Raoul Varet. The author has studied (1) the action of cyanide of mercury on bromide of zinc; (2) the action of cyanide of zinc on bromide of mercury.—On a new sugar of the aromatic group, by M. Maquenne. To inosite and quercite, the only saccharine substances hitherto obtained from benzene, the author adds a third, provisionally named β-inosite, which he obtains from a pinite derived from the resin of *Pinus lambertiana*, of Nebraska.—Synthesis of metaphenylene-diamine, by M. Alphonse Seyewitz. The author has succeeded in effecting this synthesis by heating, to 280° or 300° C., a mixture of resorcine and calcium chloride under conditions here described.—Papers were submitted by MM. A. Béhal and Choay, on the action of heat on chloral-ammonia; by M. Raphael Dubois, on the mechanism of awakening in hibernating animals; by M. E. Couvreur, on the pulmonary circulation of the frog, as affected by the excitation of the pneumogastric nerve; by M. R. Moniez, on the larva of the new species *Tænia Grimaldii*, a parasite of the dolphin; by MM. Appert and Henrivaux, on the devitrification of the ordinary glass of commerce; by MM. E. A. Martel and G. Gaupillat, on the formation of springs in the interior of the limestone plateaux of the *causses* of Languedoc; and by M. J. Thoulet, on the quantitative analysis of the fine sediment held in suspension in natural waters.

BERLIN.

Physiological Society, November 15.—Prof. du Bois-Reymond, President, in the chair.—After the appointment of officers for the year 1889-90, Dr. Virchow spoke on the spiracle gill of Selachians. With the assistance of drawings and a series of diagrams he discussed the varying arrangements and divisions of the blood-vessels which go to form the gills of Selachians; he also described the frequent occurrence, confined to certain regions of the head, of blood-vessels which are elaborately convoluted; the physiological significance of these vessels is quite unknown, but their morphological interest is so great that an extended investigation of them in other groups of animals is a matter of great importance. In all probability they are rudimentary structures, whose significance would be understood if the above extended investigations were carried out.—Dr. I. Munk spoke on the absorption of fats and fatty acids in the absence of bile in the intestine. The older classical experiments on animals with a biliary fistula had taught that, in the absence of bile, proteids and starch are digested as completely as in a normal animal, whereas, on the other hand, the absorption of fat is largely interfered with. In correspondence with this view, the later observers were of opinion that all fat which is not absorbed does not leave the body as neutral fat, but as fatty acids, and from this the conclusion was drawn that the fats of food are decomposed into fatty acids (and glycerin) before they are normally absorbed. The speaker had carried out a series of experiments on dogs with biliary fistulæ, during the past summer, with a view to clearing up several obscure points in the whole question of the absorption of fats. After he had confirmed the older views as to the normal digestion of proteids and starch, and the appearance of unabsorbed fat in the form of free fatty acids in the fæces, he proceeded to determine quan-

titatively the absorption of fat from the intestine in the absence of bile. He found, first, that in such animals there is a relatively large absorption of fat from the alimentary canal as long as they receive the fat in company with proteids and starch, but that the absorption is much less when the fat is administered—as it was in the experiments of the older observers—mixed only with proteids. It was found that the animals absorbed more than 70 per cent. of such a fat as pig's lard, whose melting-point is low, without the assistance of bile; they also absorbed an almost proportionately large quantity of the free fatty acids of the lard, thus corresponding exactly to the behaviour of normal animals, which can absorb about 94–98 per cent. of any fat whose melting-point is low, whether it be administered in the form of neutral fat or of the fatty acids which it contains. When a fat was administered whose melting-point is high—especially such a fat as only begins to soften at the temperature of the body (*e.g.* mutton fat)—the amount absorbed was considerably less, and it was still less when the free fatty acids of this fat were given with the food. The speaker pointed out, with regard to the fæces of animals with a biliary fistula, that they may be dark-coloured, or even black, on a proteid diet, and only appear light-gray in colour when carbohydrates are given with the food. This dark colour is not, however, due to any derivative of the bile-pigments, but to hæmatin. The speaker had not been able to detect, with certainty, any further advanced decomposition of the contents of the intestine in animals with a biliary fistula, neither did he observe any increase of putrefactive products, such as indol, skatol, &c., in their urine.

In our report, last week (p. 95), of the meeting of the Berlin Physical Society on October 25 (first column, fifth line from foot), *for* "waves in air 21 metres long" *read* "waves in air 2 kilometres long."

THE TEACHING OF FORESTRY.

A Manual of Forestry. By William Schlich, Ph.D. Vol. I. (London: Bradbury, Agnew, and Co., 1889.)

PROBABLY it will not for some time be generally recognized in England that forestry is a profession in the sense in which we speak of the profession of law or of medicine. And it is a bold step to publish a manual of forestry for English readers in a systematic and strictly technical form. This is the task which Dr. Schlich has undertaken, and the volume before us is the first instalment of a large work, which, when completed, will be the first comprehensive manual of forestry in the English language.

Before going out to India in 1866, Dr. Schlich had passed the examinations for the superior forest service in his own country (Hesse Darmstadt), he had been the pupil of one of the most eminent Professors of Forestry in Germany, the late Gustav Heyer, and he held a distinguished place among his fellow students. At the commencement of his career, the changes which had taken place in Hesse Darmstadt in consequence of the Austrian war were believed to affect injuriously the chances of promotion for the younger members of the forest service. This induced him to accept the offer of an appointment in India. Here he was designated at an early date for important positions, and thus, after he had served several years in Burmah, he was sent to Sind, where, under completely different conditions of climate and forest, he did excellent work. He served successively as Conservator of Forests in Lower Bengal and in the Punjab, until he rose to the post of Inspector-General of Forests. In 1885 he consented to relinquish his important position in India, in order to become Professor of Forestry at the Forest School which it had been decided to form in connection with the Royal Indian Engineering College at Coopers Hill.

The volume before us contains the general and introductory part; in a second volume the author proposes to set forth in detail the different sylvicultural operations; while the protection of forests, the utilization of timber and other forest produce, the systematic arrangement of the plans for working, and the financial aspect of forest management, will complete the work. Not the least of the advantages which will be gained by the publication of this manual will be to settle the English forest terminology. The technical terms which had been tentatively used since methodical forest management was begun in India may now be expected to receive general currency, and will be more correctly understood than before.

The primary object of the Coopers Hill Forest School is the training of officers for the Indian Forest Service, but others also may attend the forestry classes in order to qualify for the management of forests and woodlands in Great Britain and in the colonies. It may therefore be hoped that Dr. Schlich's manual will eventually promote the good management of forests in many parts of the world. In Great Britain and Ireland the author states the area of woods and forests at 2,790,000 acres, and in British India the area of Government forests at 70,000,000. No data are available for estimating the forest area in the British colonies. But the area stated is sufficient to demand the systematic teaching of forestry in England.

In the German Empire the total forest area only measures 34,346,000 acres, of which 11,243,000 acres belong to the State. Yet there are no less than nine forest schools in the different States for educating the superior officers in the State and other public forests and the principal wood managers in private estates. The books published on the subject of forestry in all its branches during the three years 1886–88 amounted to 177, or fifty-nine a year on an average. Besides these, there are ten periodicals on forestry, some quarterly, most monthly. One general association of German foresters meets annually, and ten local societies hold their meetings either annually or once in two years. And all these associations publish their transactions. Perhaps it will be urged that this large and daily-growing forest literature is not necessarily an advantage; that German foresters had better attend to the management of their forests instead of writing books. As a matter of fact, however, the management of the German forests, public as well as private, is excellent, and is improving steadily. The best proof of this is the large and steadily growing income derived from these estates by the Government, by towns and villages, and by private proprietors, and, more than that, the improved condition and the increased capital value of these properties.

A commencement, however, of forest literature has been made in the English language. The Transactions of the Royal Scottish Arboricultural Society have attained their twelfth volume, and they frequently contain papers of considerable importance. The *Indian Forester*, commenced as a quarterly by Dr. Schlich in 1875, is now a monthly magazine, of which fifteen volumes have appeared. In addition to these a number of valuable publications on different branches of forestry might be named that have been published within the last twenty-five years.

German forest literature, though it has attained such large dimensions, is of comparatively recent origin. During the eighteenth century sylviculture and the management of forestry had made great progress in many parts of the country, but the methodical and scientific treatment of the subject dates from the labours, during the first thirty years of the present century, of Hartig in Prussia, Cotta in Saxony, and Hundeshagen at Giessen. Scientific forestry in England must necessarily be built upon what has been accomplished in this respect in Germany, and with becoming modesty Dr. Schlich acknowledges that the principal German works have been his guide in the preparation of the present book. Great Britain does not stand alone in this respect. In France also the development of scientific forestry has to a great extent been based upon the progress previously made in Germany. The same may be said of forestry in Italy, Russia, Scandinavia, and other European countries.

Part I. of the manual treats of the utility of forests, directly in producing wood and other forest produce, and indirectly in influencing the climate, in the distribution of rain-water, in the preservation of the soil on sloping ground, in the binding of moving sands, and in affording shelter against winds. All these matters are clearly and ex-

haustively treated, and in regard to the climatic influence of forests the author gives a most useful summary of the researches which have been made to determine the effect of forest growth upon the temperature of air and soil, rainfall, humidity, and evaporation, in Germany, Switzerland, and France, mainly by the establishment of parallel stations, one being situated inside a fully stocked forest and the other at some distance in the adjoining open country.

Part II. sets forth the fundamental principles of sylviculture. The author maintains, with justice, that the principles of sylviculture hold good all over the world, but adds that the illustration of these principles must be taken from a limited area. For this purpose he has chosen the timber trees of Western Europe on the 50th degree of north latitude, and the countries immediately to the north and south of it—in other words, the forest trees of England, Northern France, and the greater part of Germany. These species the author does not attempt to describe; he assumes that his readers are familiar with them. The first chapter dwells upon the external conditions which influence the development of forests. He says:—

"Soil, including subsoil, and atmosphere are the media which act upon forest vegetation, and they together are in sylviculture called the 'locality.' The active agencies, or factors, of the locality depend on the nature of the soil and the climate, the latter being governed by the situation. The sum total of these factors represents the quality or yield-capacity of the locality. The forester requires to be well acquainted with the manner in which soil and climate act on forest vegetation, in order to decide in each case which species and method of treatment are best adapted, under a given set of conditions, to yield the most favourable results."

Every forester knows that on good soil, and under conditions otherwise favourable, a timber crop is heavier than one of equal age grown under less favourable conditions. In the concluding section of this chapter the author shows how one may use this fact in order to assess the quality of a locality. Numerous measurements of woods of different species and ages, grown under different conditions, have been made in Germany on a systematic plan, and from the data thus obtained yield tables have been calculated, showing the volume of timber produced at different ages on a given area by the principal species on localities of different quality classes. Using the yield tables published for the Scotch pine by Wilhelm Weise, now Professor at the Forest School of Karlsruhe, the author shows that at the ages of 50 and 120 years the volume per acre of timber only, not including faggots, in localities, which according to their yield-capacity are classed as first, second, and third class, is as follows:—

	I.	II.	III.
Cubic feet at the age of 50 years	5060	3940	2700
,, ,, 120 ,,	9060	6950	5340

The figures of these yield tables Dr. Schlich has found to a certain extent to be applicable to Scotch pine forests in England. They can therefore be used in order to assess the yield-capacity of any locality stocked with Scotch pine. Eventually, similar yield tables will doubtless be prepared for the Scotch pine and other forest trees in Great Britain, and it will then be possible with certainty to say what yield of timber may be expected from plantations made in a certain locality.

The second chapter deals with the shape and development of forest trees, but we can refer only to what the author says regarding height-growth. Building again chiefly upon researches made in Germany, Dr. Schlich explains how the different species have a different mode of height-growth. On p. 163 an instructive diagram will be found exhibiting the relative height-growth of spruce, silver fir, beech, and Scotch pine, in a locality of the first quality. At the age of 50 years the mean height attained by each species is as follows:—

Scotch pine	64 feet
Beech	60 ,,
Spruce	55 ,,
Silver fir	40 ,,

At a later age spruce and silver fir take the lead, while beech and Scotch pine remain behind in the race; and when 120 years old the order of the species stands as follows:—

Spruce	118 feet
Silver fir	108 ,,
Beech	102 ,,
Scotch pine	97 ,,

Scotch pine and beech therefore make the principal height-growth during the first period of their life, whereas spruce and silver fir continue to grow vigorously in height to a much greater age, spruce more so than silver fir. The progress of height-growth of the different species is much affected by the character of the soil, by elevation, the more or less crowded state of the wood, and other circumstances, but under otherwise similar conditions it will always be found that deep, fresh fertile soil produces much taller trees than shallow, dry, or rocky soil.

In the third chapter, which deals with the character and composition of woods, the author points out that the object of sylviculture is not to rear isolated trees, but considerable masses of trees, forming more or less crowded woods. Pure woods consist of one species only, or of one species with a slight admixture of others, whereas mixed woods contain a mixture of two or more species. The advantages of mixed woods are clearly set forth, and the author's remarks on this subject may be specially recommended to the attention of proprietors and managers of woodlands in Great Britain.

The last and most important chapter deals with the sylvicultural systems—that is, the different methods under which the creation, regeneration, tending, and utilization of woods are effected. The three well-known classes are: first, high forest, originating in seedlings, either self-sown or artificially raised; second, coppice, which regenerates itself from coppice shoots; and third, coppice with standards, a combination of seedling and coppice forest. The modifications of these three main systems are numerous, and particularly the treatment of high forest has developed in a great variety of ways. On this subject we must refer the reader to the manual. These are matters which can hardly be fully understood without opportunities for obtaining practical experience of forests treated under the various systems described. Such opportunities may, to some extent, be found in Great Britain. The high forests of larch and Scotch pine in Scotland, raised by planting, are excellent, and in some

districts Scotch pine woods are regenerated by self-sown seedlings. The oak woods of the Forest of Dean, and the beech woods on the chalk downs of Buckinghamshire, are instances of high forests with different character and different method of treatment. Most instructive, again, are the natural oak forests in Sussex—coppice, with a large proportion of standards. So are the coppice woods of ash and sweet chestnut for the production of hop-poles in Kent, and the osier beds on the banks of the Thames. The difficulty is, that the treatment of these woods is entirely empirical, and that, without authentic statistical data regarding yield in timber, regarding income and outlay, no forest can properly be used for purposes of instruction. If the student wishes fully to understand this and other portions of the excellent manual before us, he must study the forests of Germany, public and private. This may be a disadvantage, but under the circumstances of the case it cannot be helped.

Appended to the first part of the book are two treatises which will be read with interest by those who may not care to study the more technical portion of the manual. They deal with forestry in Great Britain and Ireland and in British East India. The physical configuration of India, its climate and rainfall, the distribution of the forests, and the forest policy pursued by the Government of India during the last thirty years, are clearly set forth. The protection and systematic management of its forests are matters of the utmost importance for the welfare of the millions inhabiting the British Indian Empire, of infinitely greater importance than good forest management is for Germany or other countries of Europe. Enthusiastic foresters in India have long maintained that, by improving the condition of existing forests, so as to make them more dense and compact, by extending their area, and by creating forests where none exist at present, the rainfall in seasons of drought might be increased, and famines might thus be averted. Dr. Schlich fully discusses this subject, and states several cases in which the presence of dense forest growth seems to accompany an increased rainfall; but at the same time he fully explains the reasons why a final conclusion does not seem justified. The result is that, though the local influence of forests in lowering the temperature and preserving moisture is undeniable, we are not justified in hoping for an improvement of the Indian climate. The favourable influence of forests in India upon the irrigation from wells and tanks is, however, beyond doubt, and this is a vital question.

To illustrate the effect of forest growth in protecting loose soil on hill-sides, the author mentions the Siwalik hills at the foot of the North-West Himalaya. We quote his words:—

"Anyone who has ever stood on the hills behind Hushiarpur in the Punjab, and looked down upon the plain stretched out towards the south-west, has carried away an impression which he is not likely to forget. In that part the Siwalik range consists of an exceedingly friable rock, looking almost like sand baked together. Formerly, the range was covered with a growth of forest vegetation, but a number of years ago cattle owners settled in it, and under the combined attacks of man, cows, sheep, and goats, the natural growth disappeared, while the tread of the beasts tended to loosen the soil. The annual monsoon rains, though not heavy, soon commenced a process of erosion and of carrying away the surface soil. Gradually, small and then large ravines and torrents were formed, which have torn the hill range into the most fantastic shapes, while the *débris* has been carried into the plains, forming, commencing at the places where the torrents emerge into the plain, fan-shaped accumulations of sand which reach for miles into the plain, and which have already covered and rendered sterile extensive areas of formerly fertile fields. Indeed, one of these currents or drifts of sand has actually carried away a portion of the town of Hushiarpur. The evil has by no means reached its maximum extent, and if curative measures are not adopted at an early date, the progress of transporting the hill range into the plain will go on, until the greater part of the fertile plain stretching away from its foot has been rendered sterile."

The author might have added the denuded hills, and the rivers, formerly navigable, but now silted up, in the Ratnagiri district of Western India, and other similar instances.

That a country so populous as India requires immense quantities of timber, bamboos, and firewood, goes without saying. Among other articles of forest produce, cattle fodder is an important item. In the drier portions of the country the supply of grass, particularly during seasons of drought, is more plentiful under the shelter of trees than out in the open. In times of scarcity, grain can easily be carried long distances to provide food for the people, while cattle fodder cannot be so easily carried. As a matter of fact, where forests have been formed and protected in the drier parts of India, they have proved a great help in enabling the people to maintain their cattle in times of drought and scarcity.

In India the duty of taking action necessarily devolved upon the State. The result has been the formation of extensive forest estates, called reserved forests, which at present, the author states, aggregate 33,000,000 acres, or three times the area of State forests in the German Empire. If forest matters in India continue to be properly managed, these estates will not only secure the well-being of the people, but will be an important source of strength to the Government, financially and otherwise. As yet, the revenue which they yield is insignificant in relation to their extent. But it is growing steadily. Dr. Schlich shows that during the three years 1864-67 the average annual net revenue from the Government forests amounted to £106,615, and during the five years 1882-87 to £384,752; and he states it as his opinion that, twenty-five years hence, the net surplus will be four times the present amount. More important, however, than the annual revenue is the steadily increasing capital value of these Government forest estates.

In Great Britain the aspect of affairs is different. The small area of the Crown forests, burdened as they are with prescriptive rights, cannot reasonably be expected materially to help the development of systematic forest management. But there are over 2,500,000 acres of woods and forests in the hands of private proprietors, and there are 26,000,000 acres of barren mountain land and waste, a portion of which might be planted up. Proprietors, as a rule, desire to augment their income and to increase the capital value of their estates. In many cases this might be effected by a more systematic management of their woodlands, and by the planting up of waste lands. The chief obstacle to progress in this direction is the low

price of timber and the high rent at present obtained by the letting of grouse moors and deer forests.

Upon data which cannot be gainsaid, Dr. Schlich has based important calculations, which will be found on pp. 17-19. Space forbids the discussion of details, but the result is that Scotch pine forests cannot be expected to yield more than 2½ per cent. on the capital invested (the value of the land and of the growing crop).

"All land, therefore, which can be let for the raising of field crops, for shooting, or other purposes, at a rental equal to, or upwards of, 2½ per cent. of the capital value of the land, had better be so let. On the other hand, land which would realize a rental of less than 2½ per cent. of its value, may with advantage be planted with Scotch pine or other similarly remunerative trees."

These conclusions are based upon circumstances as they exist at the present time. But a change of circumstances is not impossible. The author points out that 6,000,000 loads of timber are imported annually into the United Kingdom from Europe and North America, and that only a small portion of the forests which furnish this large supply are under systematic management and control. It may be regarded as certain that the supply from Sweden and Norway and from North America, amounting at present to nearly 4,000,000 loads a year, will continue to diminish, and, under the circumstances of the case, the necessary result of such diminution will eventually be a rise in the price of timber. Again, if proprietors of woodlands in England and Scotland were in a position to offer large quantities of home-grown timber of good quality for sale, regularly at stated seasons, timber traders would make their arrangements accordingly, and in many cases better prices would be obtained. Firewood is at present almost unsaleable in the United Kingdom, but if—and this may happen—the price of coal should rise considerably, firewood would in some districts become an article of general consumption, as it was 150 years ago, and to some extent this would improve the money yield of woodlands.

It is not too much to say that the publication of Dr. Schlich's manual will give a powerful impetus to systematic forest management in the United Kingdom, in India, and in the vast colonies of the British Empire—in fact, wherever the English language is spoken.

D. BRANDIS.

FERREL'S THEORY OF THE WINDS.

A Popular Treatise on the Winds. Comprising the General Motions of the Atmosphere, Monsoons, Cyclones, Tornadoes, Waterspouts, Hailstorms, &c. By William Ferrel, M.A., Ph.D., &c. (New York: John Wiley and Sons. London: Macmillan and Co. 1889.)

NUMEROUS as are the popular treatises on various branches of phenomenal meteorology that have appeared during the last quarter of a century, English literature has hitherto been singularly deficient in elementary works treating of the physical and mechanical processes of the atmosphere from a theoretical point of view, and suited to the capacity of the average student. Those versed in the higher mathematics may indeed find all they require in such modern works as Sprung's "Lehrbuch der Meteorologie," and Ferrel's "Recent Advances in Meteorology," the high merit and originality of which last are somewhat veiled under its more obtrusive title—"Part 2 of the Report of the Chief Signal Officer of the [U.S.] Army for 1885." But these works are hardly suited for popular instruction; and for that large class of students whose mathematical acquirements are more limited, but who nevertheless desire to understand the movements and internal changes of the atmosphere, and to interpret them rationally in accordance with mechanical and physical laws, there has hitherto been little guidance, save such as they may obtain from casual references to them in works devoted to the general teaching of these sciences. It is perhaps in consequence of this divorce of the deductive from the inductive treatment of meteorological subjects that the contributions of English observers to the science of meteorology bear but an insignificant proportion to the labour expended on observational work, and that so much of this work is abortive, and practically of little value, owing to the absence of guiding and suggestive theoretical knowledge.

It is, then, with no ordinary degree of satisfaction that we hail the publication of Prof. Ferrel's treatise, the title of which heads this notice. As the originator and discoverer of many of the most important problems dealt with in these pages, no one could be better fitted to explain them in terms suited to general comprehension, and this task he has performed with a completeness and lucidity which leave but little to be desired. The work is, as it professes to be, a "popular" treatise, but popular only in the higher sense of the word. A system of movements so complex as those of the earth's atmosphere cannot be made clear to anyone who is not capable of following a chain of close reasoning, or who is not prepared to bring to the study that concentrated attention that is requisite to master any problem in deductive science. But, these being granted, no further demand is made on the student than some familiarity with the elements of algebra, and the simplest conceptions of plane trigonometry and kinetics. The action of the mechanical and physical forces that determine and regulate the wind system of the globe is clearly explained in the first two chapters of the work.

The most important and original portion of the book is that which deals with the general circulation of the atmosphere, in relation to which the cyclones and anticyclones that cause the vicissitudes of local weather are but matters of subordinate detail. The magnitude of the work achieved by Prof. Ferrel in this field has hitherto been recognized only by the few. It is not too much to say that he has done for the theory of atmospheric circulation that which Young and Fresnel did for the theory of light; and that the influence of his work is not more generally reflected in the literature of the day, must be attributed to the want of some popular exposition of the theory.

Starting with the fundamental conditions of a great temperature difference between equatorial and polar regions and a rotating globe, and postulating in the first instance a uniform land or water surface, it is shown how the convective interchange of air set up by the former must result in producing two zones of maximum

pressure in about lat. 30° in both hemispheres, two principal minima at the poles, and a minor depression on the equator, together with strong west winds in middle and high latitudes, and an excess of easterly winds in equatorial regions. The two tropical zones of high pressure determine the polar limits of the trade winds, and the whole system oscillates in latitude with the changing declination of the sun. Further, as a consequence of the fact that the great mass of the land is restricted to the northern hemisphere, whereas the southern hemisphere presents a comparatively uninterrupted sea surface, on which the retarding friction is less than in the northern hemisphere, the west winds of middle and high latitudes are much stronger in the latter than in the former, and by their lateral pressure cause a slight displacement of the tropical zones of high pressure and the equatorial zone of low pressure to the north of their normal positions on a hypothetical uniform terrestrial surface.

The great modification and extension of Hadley's theory thus introduced by Prof. Ferrel depends mainly on two points of the first importance. By all previous writers it was assumed that a mass of air at rest relatively to the earth's surface on the equator, if suddenly transferred to some higher latitude—say, *e.g.*, 60°—would have a relative easterly movement in that latitude equal to the difference of rotary velocities on the equator and on the 60th parallel, or about 500 miles an hour, the difference being proportional to that of the cosines of the latitudes. This, however, would be true only in the case of rectilinear motion. In reality, as Prof. Ferrel was the first to demonstrate, the mass of air would obey the law of the preservation of areas, like all bodies revolving under the influence of a central force, and its relative eastward velocity in latitude 60° would be 1500 miles an hour, being as the difference of the squares of the cosines. If, on the other hand, any mass of air at rest in latitude 60° were suddenly transferred to the equator, it would have a relative westerly movement of 750 miles an hour, and any mass of matter whatever moving along a meridian is either deflected—or if, like a railway train or a river between high banks, it is not free to yield to the deflecting force, presses—to the right of its path in the northern, and to the left in the southern, hemisphere.

The second point first established by Prof. Ferrel is that, in virtue of centrifugal force, this deflection or pressure to the right in the northern, and to the left in the southern, hemisphere is suffered in exactly the same degree by bodies moving due east and due west, or along a parallel of latitude, and therefore also in all intermediate azimuths.

From the first of these principles it will be readily seen why the west winds of middle latitudes are so much stronger than the easterly winds of the equatorial zone; and from the second, how these opposite winds, by their mutual pressure, produce the tropical zones of high barometer and the polar and equatorial regions of low barometer.

In subsequent chapters are discussed the modes in which the general circulation of the globe affects the climates of different latitudes by determining the distribution of rainfall in wet and dry zones, and inequalities of temperature through the agency of marine currents. Also the causes that modify and disturb the regularity of the ideal system, the chief of which is the mutual interaction of expanses of land and sea. The general excellence of these demonstrations is indisputable, but we have marked one or two passages which appear to us to be of doubtful validity, and which we recommend to the reconsideration of the author when the time comes, as we doubt not it will ere long, for the issue of a second edition of his work.

The first point to which we would take exception is what seems to us the too great influence ascribed to mountain-chains in deflecting the great atmospheric currents. That they deflect the surface winds, like other irregularities of the surface, and in proportion to their magnitude, is, of course, a matter of universal experience; but, in the absence of other causes operating to produce a diversion of the greater currents, their action in this respect appears to us to be merely local. As an instance we will take the case of the Western Ghats of India, an escarpment from 3000 to 7000 feet in height, running athwart the direction of the summer monsoon of the Arabian Sea. The wind charts of the Arabian Sea, issued by the Indian Meteorological Office, show no appreciable deflection of the monsoon wind on the windward face of this range; and if the same cannot be asserted of the corresponding wind in the north of the Bay of Bengal, where it impinges on the coast range of Arakan, it is evident that the deflection of this current to north, and eventually to north-west, is caused by the indraught towards the heated plains of Northern India.

We believe that a similar explanation will be found to hold good in all the more conspicuous cases cited by Prof. Ferrel. Thus, at p. 183 he says:—

"The air of the lower strata of the atmosphere in the trade-wind zone of the North Atlantic, having a westerly motion, and impinging against the high table-lands and mountain-ranges of Mexico, is deflected around towards the north over the south-eastern States, and up the Mississippi valley into the higher latitudes, where it combines with the general easterly flow of these latitudes, and adds to its strength. This completely breaks up the continuity of the tropical calm belt and dry zone, so that, instead of a dry region with scanty rainfall, such as is found in North Africa, Arabia, Persia, Beloochistan, and Cabul, we have on the same parallels in the southern and eastern United States a region of abundant rainfall, and all the way up the Mississippi valley and in the interior of the continent there is much more rain than in the interior of Asia."

Taking this passage as it stands, or only together with the immediate context, it might be understood to imply that the author ascribes this great diversion of the winds of the Gulf of Mexico, together with all the rainfall they bring to the southern States of America, solely to the influence of the comparatively low mountain-chain of Central America. That such, however, is not his meaning is evident from his subsequent remarks on p. 215, where, in describing the monsoons of North America, after noticing the high temperature of the land area in summer, he says:—

"On the southern and south-eastern coast, in connection with the deflection referred to [in the passage quoted above], it causes the prevailing winds to be southerly and south-easterly, instead of north-easterly, as they would otherwise be in these trade-wind latitudes."

In point of fact, as may be seen on Dr. Hann's charts for January and July, in the new edition of Berghaus's "Physical Atlas," the diversion of the trade-winds of the Gulf of Mexico, northward up the Mississippi valley takes place only in the summer, and is an effect of the same agency, viz. the heating of the northern continents that breaks up the high-pressure zone of the northern tropic into two anticyclones, one in each of the great oceans, and it is the juxtaposition of the Atlantic anticyclone and the Mexican cyclonic depression that determines the course of the winds and the resulting rainfall. To judge from the case of the Western Ghats, we think it may be safely concluded that, if there were no mountain-chain to the west of the Gulf, the results would not be greatly different. All the other instances quoted, illustrative of the diversion of great currents by mountain-chains, except such as are purely local, appear to us to be really due to other and similar causes.

In treating of the monsoons, Prof. Ferrel points out with perfect justice that their strength depends on the form of the land, and that they blow strongly only where the interior of the country is high and mountainous. But when he adduces Persia as an illustration of the negative case, we are unable to admit its relevancy. At p. 199 he observes:—

"In accordance with the preceding view of the principal cause of monsoons and land and sea breezes, it is seen from observation that all the great monsoons and the strongest land and sea breezes are found—the former in countries and on oceans adjacent to high mountain-ranges, and the latter along coasts with high mountains in the background. Neither the heated interior in summer of the Great Sahara of Northern Africa, nor of Arabia and Persia, which is considered the warmest region on the globe, causes, during this season of the year, any great indraught of air. It is true that at this season the north-westerly winds prevail a little more on the north-west coast of Africa and the ocean adjacent, due, no doubt, to the influence of the highly-heated desert of the Sahara; but over Arabia and Persia the north-west winds continue to blow almost incessantly, during June and July, away from the interior toward the Arabian Sea. . . . The monsoon influence, therefore, of countries mostly level, without an elevated interior, however highly they may become heated in summer or cooled in winter, is not very great."

But the interior of Persia is a part of the great table land of Iran, and, to quote the description of Sir Oliver St. John, "its average height above the sea may be about 4000 feet, varying from 8000 or higher in certain of the outer valleys to not more than 500 in the most depressed portions of its centre." Its average elevation is therefore much greater than that of the interior of India, very much greater than that of the Indo-Gangetic plain, which is the goal of the Indian monsoon, and, as a glance at the map will show, it is not deficient in mountains. The explanation of the fact that, instead of attracting the monsoon from the Arabian Sea, it is itself swept by north-west and west winds—blowing, not, indeed, towards the Arabian Sea, but towards the lower Indus valley—must then be sought for elsewhere. The true explanation appears to us to lie in a combination of causes. Partly, perhaps, in the latitude, which brings it within the zone of the strong easterly current of extra-tropical regions, which, by its right-handed pressure, must resist any indraught from the Arabian Sea; but chiefly in the fact that any tendency that the heated highlands of Persia may have to create such an indraught is overborne by the stronger set towards India. For the latter country reaches far down into the tropics, and the centre towards which the monsoon blows must be determined by the resultant of all the temperature gradients of the whole heated region. An eastward direction having been given to the monsoon at the outset, its strength in that direction is greatly increased by the energy set free in the Indian monsoon rainfall.

This question is one of more than theoretical importance. These west winds of Persia and Afghanistan are the dry winds of Northern and Western India, and when they prevail beyond their normal limits, over the north of the Arabian Sea and a great part of India itself, to the exclusion of the rain-bearing current, they bring the drought and consequent dearth that have made India so disastrously notorious for its famines. Possibly, the explanation of their abnormal extension may be looked for in those oscillations of the great polar cyclonic systems to which Prof. Ferrel alludes at p. 339 of his work.

Cyclones and tornadoes are treated at great length, each of these subjects occupying more than one hundred pages of the book; and in connection with the latter is given the author's theory of the formation of hail, a subject which has hitherto been less understood than almost any other phenomenon of the atmosphere. It will be best given in the author's own words:—

"In the ascending current of a tornado, as in that of the equatorial calm belt, or of a cyclone, the rain-drops are formed down in the cloud region, and carried upward until they become too large to be supported by the current and so fall to the earth. . . . In a tornado, however, the ascending current is often so strong that the rain is supported until, by the blending of the small drops by coming in contact, very large drops are formed, and the strong ascending currents often extend so high that these large drops are carried away up into the region of freezing temperature. . . . There they are frozen, and after having been carried up and outward above to a distance from the centre, where the ascending current is not strong enough . . . to keep them up, they slowly descend, and receiving additions of ice as they fall, as long as their temperature remains below zero, . . . they finally fall to the earth as solid hailstones"

The concentric coatings so commonly observed in large hailstones are explained by these hailstones being carried again and again into the vortex by the strong indraught in the lower part of the storm-cloud, the theory being that every hail-cloud is a tornado, although it may not reach down to the lower atmosphere. The vapour being condensed as water in the lower part of the vortex, which is frozen at a higher level, and as snow in the upper part, each pair of coatings indicate an additional ascent through the storm-cloud. This view, which, even at first sight, seems far more reasonable than any previous theory, has received unexpected confirmation from the experience of more than one adventurous balloonist, more especially that of Mr. John Wise, whose fate it was to be drawn seven times successively into the vortex of a hail-cloud, and carried up repeatedly until the balloon was thrown out at the top. The account is, unfortunately, too long for extracting.

From what has been said, it will be apparent that Prof. Ferrel's book enters very fully into the many important topics enumerated in the title. Indeed, its subject-matter covers very much of the ground of which modern meteorology usually takes cognizance, and in the thoroughness of its treatment we know of no modern work in our language that can be brought into comparison with it.

H. F. B.

A NEW ATLAS OF ALGÆ.

Atlas deutscher Meeresalgen. Heft I. Von Dr. J. Reinke (Berlin: Paul Parey, 1889).

THE German Government, operating through the Kommission zur wissenschaftlichen Untersuchung der deutschen Meere, has undertaken to bear the cost of producing this sumptuous "Atlas" in the interests of fishery, and students of phycology have to thank an economic aspect of their study for a very remarkable addition to the literature of it. Similarly, we are indebted to the United States Fish Commission for the publication of Prof. Farlow's "New England Algæ."

It may be said at once that Dr. Reinke's "Atlas" is a success in every way, its level being that of Bornet and Thuret's "Études Phycologiques." From the point of view of *technique*, the plates are splendidly done, and the rest of the publication is worthy of them. This first part contains twenty-five quarto plates, and the text belonging to them consists of descriptions of the Algæ figured and special descriptions of the illustrations. Speaking not merely from an inspection of the book, but from a knowledge of the material of much of it communicated by Dr. Reinke to the British Museum, I do not hesitate to state that every one of these figures has great value to phycologists. They are not mere portraits of Algæ, taken from specimens more or less at haphazard, as is too much the fashion, but they represent faithfully characteristic stages in the development of the organisms in point. What is commonly termed "microscopical detail" fills the "Atlas," and one can hardly imagine it better done. In this portion the author (who has had the assistance of Dr. F. Schütt and P. Kuckuck) deals prominently with the Phæophyceæ, which, it is well known, are his particular study at present. Many of them are types of his own discovery, and generally unknown to workers in this field until this satisfactory introduction to them. Since they are of special importance to our native phycologists as Algæ of the North Sea and Baltic, a list is given of them :—

Halothrix lumbricalis, Kütz., *Symphoricoccus radians*, Rke., *Kjellmania sorifera*, Rke., *Asperococcus echinatus*, Mert., var. *filiformis*, Rke., *Ralfsia verrucosa*, Aresch., *R. clavata*, Carm., *Microspongium gelatinosum*, Rke., *Leptonema fasciculatum*, Rke., var. *uncinatum*, var. *majus*, var. *flagellare*, *Desmotrichum undulatum*, J. Ag., *D. balticum*, Kütz., *D. scopulorum*, Rke., *Scytosiphon pygmæus*, Rke., *Ascocyclus reptans*, Cr., *A. ocellatus*, Kütz., *A. balticus*, Rke., *A. fæcundus*, Strömf., var. *seriatus*, Rke., *A. globosus*, Rke., *Ectocarpus sphæricus*, Derb. et Sol., *E. Stilophoræ*, Cr., *E. repens*, Rke., *E. ovatus*, Kjellm., var. *arachnoideus*, Rke., *Rhodochorton chantransioides*, Rke., *Antithamnion boreale*, Gobi, var. *balticum*, Rke., *Blastophysa rhizopus*, Rke., *Epicladia Flustræ*, Rke., *Cladophora pygmæa*, Rke., *Pringsheimia scutata*, Rke.

It may be anticipated that a fair number of the novelties among these so-called "German Algæ" (the title reminds one of the "Protestant trout") may be found on our own coasts.

It should be mentioned that more systematic detail with reference to many of these is to be found in the author's "Algenflora des Westlichen Ostsee" (Berlin, 1889).

The author very properly calls attention to the fundamental importance of a thorough knowledge of marine Algæ to fishery, since the plant world prepares by its organs of assimilation the food of the animal world in the sea. The German Commission deserve the highest praise for the enlightened view of their functions embodied in this undertaking, and no biologist will grudge the warmest encouragement to Dr. Reinke in his work. It is anticipated that the book, when complete, will contain a hundred plates, with the accompanying text. In these days, when the most unmitigated rubbish frequently comes to us with highly pretentious illustrations, the student has learned to be on his guard against "prepossessing appearances." No *plate manufacture*, however, can produce the welcome impression of weight and importance stamped on this "Atlas," gained to a great extent by the fact that Dr. Schütt and Herr Kuckuck, who have drawn the plates, have given us the work of skilful botanists, and not that of draughtsmen only.

G. M.

OUR BOOK SHELF.

Die mikroskopische Beschaffenheit der Meteoriten erläutert durch photographische Abbildungen. Von G. Tschermak. (Stuttgart: E. Schweizerbart'sche Verlagshandlung [E. Koch], 1883-85.)

Die Structur und Zusammensetzung der Meteoreisen erläutert durch photographische Abbildungen geätzter Schnittflächen. Von A. Brezina und E. Cohen. (Stuttgart: E. Schweizerbart'sche Verlagshandlung [E. Koch], 1886-87.)

Die Meteoritensammlung des k. k. mineralog. Hofkabinetes in Wien. Von A. Brezina. (Wien: Alfred Hölder, 1885.)

THE above three works together provide for the student a rich treasury of information relative to the characters of meteorites. The first two illustrate, by the aid of photography, the structure and composition of the more typical meteoric stones and irons respectively. The work dealing with the meteoric stones is complete in three parts, including 25 large plates, and has been undertaken by Prof. Tschermak, who had charge of the Vienna Collection of Minerals from 1869 to 1877. Of that which relates to the meteoric irons only two parts have as yet appeared, but they comprise no fewer than 24 large plates: it is undertaken jointly by Dr. Brezina, who succeeded Prof. Tschermak in the keepership of the Vienna Collection, and by Prof. E. Cohen, of Greifswald, whose series of micro-photographs of sections of terrestrial minerals and rocks is so well known.

Photography has rarely been applied to a more satisfactory purpose than the multiplication of exact representations either of transparent meteoritic sections, or of etched meteoric irons as seen with the unassisted eye or when magnified by means of the microscope. Meteoritic falls are rarely so large that the market is flooded with

illustrative specimens; and, indeed, a good collection of typical meteorites is inaccessible to most students. But, further, meteoric irons are very prone to deteriorate, through oxidation, and the perpetuation of the characters of a freshly etched face is thus especially to be desired. The excellence of the photographs is beyond all praise. The details, whether of the chondritic structure or of the Widmanstätten figures, are most beautifully shown. A brief description of the salient features of the sections is furnished with each plate.

The third work is nominally a Catalogue of the Vienna Meteorites, but, by reason of the completeness of that collection, is virtually a survey of the petrographical characters of the meteorites of all the known falls. The classification adopted is in the main that suggested by Gustav Rose in 1864, and developed by Tschermak in 1872 and 1883. The detailed description and definition of the groups is preceded by a history of the Vienna Collection, and also by a sketch of the various theories which have been proposed relative to the mode of formation of meteorites. As a result of his microscopical researches, Dr. Brezina supports the view that the structural features of meteorites are due to hurried crystallization, and not to a slow agglomeration of fragmentary matter. Dr. Brezina adds a chronological list of the meteorites preserved in the known collections, and also a lengthy index of names, synonyms, and localities. The work extends over 126 pages, and is accompanied by four plates. L. F.

Introduction to Chemical Science. By R. P. Williams A.M., and B. P. Lascelles, M.A., F.C.S. (London: Ginn and Company, 1889.)

THERE could hardly be a more concise and well-digested summary of elementary chemical principles and applications than that contained in this work. It is a manual intermediate between the natural philosophy primer and the minute and detailed text-book, and fills the gap pointed out in the Report on Chemical Teaching of a British Association Committee in 1888. Hence, as an outline of chemical science to be filled up in greater detail from larger works, and as an introductory text-book, this volume will be found exceedingly useful. The experiments described are such as should be performed by everyone beginning the study of chemistry, and would also serve as an excellent introduction to a course of qualitative analysis. In addition to the treatment of metals and non-metals, the work includes chapters on organic chemistry, and others on photographic chemistry, the chemistry of rocks, and electro-chemistry. Indeed, Mr. Williams, the author of the American edition, and the reviser, Mr. Lascelles, may claim to have produced a most comprehensive little work, and one deserving considerable commendation.

The Cradle of the Aryans. By Gerald H. Rendall, M.A. (London: Macmillan and Co., 1889.)

THE question as to the primitive home of the so-called Aryan race has lately excited so much interest that many students must have wished for a short and clear account of the controversies relating to the subject. This is exactly what Prof. Rendall supplies in the present essay, the substance of which was originally communicated to the members of the Liverpool Literary and Philosophical Society. Prof. Rendall accepts Penka's theory that the Aryans were a European people who, at the close of the glacial epoch, followed the ice northwards, and settled in Scandinavia; and that Scandinavia was the centre from which, at various subsequent periods, groups of the Aryan race were dispersed. All the arguments marshalled by the German writer in favour of this hypothesis are here briefly and effectively stated. The philological part of the case is presented in a more scholarlike spirit by Prof. Rendall than by Penka himself, whose rash philological conjectures have prevented a good many people from doing full justice to the weight of his anthropological and ethnological evidence.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Mr. Cope on the Causes of Variation.

MR. E. D. COPE'S letter in NATURE of November 28 (p. 79) is a fair sample of his writings on biological theory, in so far as I am acquainted with them.

Mr. Cope proposes to teach Mr. Wallace and others the first principles of both logic and biology. The tone of his letter encourages a similar frankness in reply. Mr. Cope must not take it amiss when he is charged with two of the gravest faults of which a critic can be guilty—namely, complete misapprehension of the matter which he is attempting to criticize, and no less complete ignorance of the recognized and elementary facts of the branch of science to which that particular matter relates. I do not hesitate to assert that Mr. Cope puts forward an argument which could not possibly be entertained by anyone who is acquainted with the most notorious and admitted facts of heredity and variation. I venture to express myself thus emphatically, because it is a matter for sincere regret that American biology should at this moment be identified with what is sometimes called "a school of philosophy" which owes its distinction to a deliberate ignoring of the writings of Mr. Darwin. By all means let us have discussion and criticism of Mr. Darwin's conclusions, but let it be understood that those who enter upon such discussion have at any rate an elementary acquaintance with the works of Mr. Darwin himself, if not with those of Weismann and Wallace; otherwise, much time and much of your valuable space will be wasted.

That Mr. Cope has not the necessary elementary acquaintance with the admitted facts of heredity and variation will appear from what follows. The discussion in which he has intervened is one as to whether certain structural peculiarities exhibited by flat-fish are due to the transmission to their offspring of a form and position of parts *acquired* by muscular efforts by the ancestors of flat-fish, or whether these given structural peculiarities suddenly appeared in the ancestors of flat-fish as a "congenital variation" having no adaptive relation to any efforts or experiences of a preceding generation, and were advantageous to their possessors, so that the individuals thus born were favoured in the struggle for existence, survived to maturity, and transmitted their peculiarity to some of their offspring with such intensification as is found experimentally to be the result of breeding from parents both of which possess a given congenital peculiarity.

The question raised is, in short, whether in this case Lamarck's *hypothesis* of the transmission of acquired characters is the necessary explanation, or whether the case can be explained by the action of the *known* causes (not hypothetical causes) on which Mr. Darwin founded his theory of the origin of species, viz. the occurrence of congenital variations unrelated to any like variations in parents or ancestors, and the selection and intensification of such variations in subsequent breeding. There has been here no ambiguity—such as unfortunately arises sometimes when like questions are discussed—as to the sense in which the term "acquired characters" is used. It is clear enough that by the "acquired characters" of a parent we do not mean characters congenital in the parent, but expressly exclude them; it is clear that we refer on the contrary (as did Lamarck) to new characters acquired by the parent as the direct consequence of the action of the environment upon the parental structure, and exhibited by that parent as definite measurable features.

Now let us consider Mr. Cope's contribution to the discussion. He accuses Mr. Wallace—who is one of those who refuse to adopt Lamarck's gratuitous hypothesis of the transmission of acquired characters—of being guilty of the sin of "non-sequitur" and "paralogism." He then proceeds to make a general statement, the truth of which neo-Darwinians (or post-Darwinians, or anti-Lamarckians), in common with all men, recognize,

although Mr. Cope offensively implies that they do not, viz. "Selection cannot be the cause of those conditions which are prior to selection: in other words, a selection cannot explain the *origin* of anything." How can Mr. Cope presume to tell us this? Who has ignored it? when? and where? Mr. Cope does not seem to be aware of the fact that the anti-Lamarckians attach great importance to the existence of congenital variation, that Darwin himself has written at length on the subject, and that Weismann has developed a most ingenious theory as to the relation of fertilization and its precedent phenomena to this all-important factor in evolution.

Mr. Cope puts aside all that has been done on that subject, or else is ignorant of it, and calmly lays down the following proposition: "If whatever is acquired by one generation were not transmitted to the next, no progress in the evolution of a character could possibly occur. Each generation would start exactly where the preceding one did." The full significance of this sentence can only be apprehended when it is understood that Mr. Cope believes that progress in the evolution of a character *does* occur. The statement therefore amounts to this: (1) that whatever is acquired by one generation is transmitted to the next; and (2) that the only possible explanation of the fact that a new generation does not exactly resemble its parents at a corresponding age is that the parental generation has transmitted to its offspring particular features acquired by it between birth and maturity.

I doubt whether Mr. Cope will find any other naturalist—even the most ardent Lamarckian—to join him in these assertions.

With regard to the first, it is hardly necessary to say that it has never yet been shown experimentally that *anything* acquired by one generation is transmitted to the next (putting aside parasitic diseases); and as to *everything* ("whatever") being so transmitted, every layman knows the contrary to be true. Children are not born with the acquired knowledge of their parents. If there were no other explanation offered of offspring varying from their parents at a like age than the hypothesis of transmission of characters acquired by the parents on their way through life by the action of the environment, this hypothetical explanation would still be quite insufficient to account for the fact that the individuals of one brood vary enormously as compared with one another, a fact which points to the individual germs (egg-cells and sperm-cells) as the seat of the processes which result in variation, and not to the parental body which is the common carrier of them all. Assuredly these broods demonstrate that *all* the acquired characters are not transmitted to *all* the offspring.

With regard to the second proposition which Mr. Cope's statement contains, experimental fact is directly opposed to its truth. As cited by Darwin on p. 8 of the first edition of the "Origin of Species," Geoffroy St. Hilaire showed that "unnatural treatment of the embryo causes monstrosities; and monstrosities cannot be separated by any clear line of distinction from mere variations." Mr. Darwin himself was "strongly inclined to suspect that the most frequent cause of variability may be attributed to the male and female reproductive elements having been affected prior to the act of conception." What he meant by "being affected" is explained at greater length in the "Animals and Plants under Domestication," where, in chap. xxii., there is a long discussion of the causes of variability, the conclusions of which are supported by an array of observed facts which Mr. Cope cannot be permitted to ignore at his pleasure. Mr. Darwin there gives solid reasons (as was his wont) for holding that variability results from the conditions to which the parents have been exposed: changes of any kind in the conditions of life, even extremely slight changes, often suffice to cause variability. But Mr. Darwin's examination of the facts did not lead him to conclude that the bodily characters acquired by the parents as the result of changes were those which manifested themselves as variations in the offspring. On the contrary he showed that the effect of changed conditions, of excess of nutriment, and of the crossing of distinct forms, is a "breaking down," as it were, of the hitherto fixed characters of the race, leading to the reappearance of long-lost characters and to the appearance of absolutely new characters, the new characters having no more (and perhaps not less) relation to the exciting cause which acted through the parent than has the newly-formed pattern in a kaleidoscope to the tap on the kaleidoscope tube which initiated the rearrangement.

For Mr. Cope to complain of the methods of reasoning of post-Darwinians, and at the same time without any reasoning at all to assert (as he does, not directly but by implication) that there is no such thing as "congenital variation" or "sporting," is not quite satisfactory. When it is asserted that every feature by which a young animal differs from the structure of its parents at a corresponding age must have been acquired by one or other of the parents as actual structural features, and so transmitted as an acquired character to the offspring, the whole world of fanciers, horticulturists, farmers, and breeders, is ready with its unanimous testimony to contradict the assertion.

Let me say, in conclusion, that, as Mr. Wallace has pointed out, Mr. Darwin did not consider that variability in a state of nature was either so general or so wide in its range as later observations and reflections lead us to believe it to be. Mr. Darwin studied those causes which are found by practical gardeners and breeders to be favourable to excessive variation in animals and plants under domestication. He showed clearly that the resulting variations had no adaptive relation to the exciting causes, and were manifested in the structure at birth of a new generation, and not in that of the generation subjected to the exciting cause. No one has yet been able to give an adequate account of the frequency and range of variation of any number of animals or plants in a state of nature, because natural conditions destroy, on the average, all individuals born of two parents—except two—before maturity is reached, and those two are naturally selected in consequence of their adhesion to the specific type.

There can be no doubt from a consideration of the facts cited by Darwin that, whilst variation often is reduced to a *minimum* in natural conditions which remain constant, natural variations of conditions can and do occur, which excite the germ-cell and sperm-cell, or their united product, to vary as in conditions of domestication. There can be no doubt that there was in Mr. Darwin's mind the conception of a definite relation between two effects arising from changed conditions: the one being the disturbance of the equilibrium of the organism and its consequent production of variations; the other being the new requirements for survival; in fact, there seems to be, as it were, at once a new deal and new rules of the game. It is not difficult to suggest possible ways in which the changed conditions shown to be important by Darwin could act through the parental body upon the nuclear matter of egg-cell and sperm-cell, with its immensely complex and therefore unstable molecular constitution, so as to bring about *variations* (arbitrary, kaleidoscopic variations) in the ultimate product of the union of the remnant of the twice-divided threads of the egg-nucleus with the nuclear head of a spermatozoon. The wonder is, not that variation occurs, but that it is not excessive and monstrous in every product of fertilization. And yet Mr. Cope writes from the other side of the Atlantic to assert that there is no possible cause of departure from parental type in offspring, excepting that assumed in Lamarck's unproved, improbable speculation! E. RAY LANKESTER.

December 7.

Protective Coloration of Eggs.

SOME years ago an idea similar to that of your correspondent, Mr. Grensted (November 21, p. 53), occurred to me, as regards the protective coloration of eggs; and, curiously enough, the red-backed shrike was one of the birds whose eggs I selected for special observation. My experience has been that the ground colour of these eggs is quite arbitrary. I fear that I cannot furnish data, as I ought; but I well remember that I found in Sussex a rather abnormally pale clutch of eggs in a very dark nest; and that I regarded this, at the time, as completely doing away with my hypothesis. The evidence that I got from other, less striking instances, told about equally for and against.

Another egg, whose variations I watched pretty closely, was that of the yellowhammer. Apart from differences of marking, the ground-colour of this egg varies from pure or pinkish white, to a white rather deeply suffused with purplish-red or olive-brown. But in this case, again, the correspondence of colour between the egg and its surroundings could not be made out at all satisfactorily.

A pale and little-marked specimen of the egg of the spotted flycatcher, that was brought in to me one spring at Malvern, suggested to me that it would be worth while to observe the variations here also. But I again failed to arrive at any conclusion.

clouds; although, according to the best of my recollection, luminous filaments seemed to extend from the clouds for a short distance into the span of the arch. EVAN MCLENNAN.

Brooklyn, Iowa, U.S.A., November 22.

Electrical Figures.

I RECENTLY noticed a pretty form of electrical discharge, which has probably been described before, but was new to me. Perhaps one of your readers will be able to refer us to an account of it.

The poles of a Voss machine are put very near together: a plate of ebonite $\frac{1}{16}$ inch thick is placed between them. As the machine works, a succession of delicate ramified discharges run over both surfaces of the plate: they are bright green, and each crooked line is discontinuous—a series of dashes, as if stitched out in silk, now above and now below the surface.

Winchester College, December 6. W. B. CROFT.

NEW DOUBLE STARS.

THE highest quality of seeing, as of acting or of thinking, needs initiative. A mental impulse is the spring of discovery, even by a purely visual process. The mind prompts the eye, interprets what it suggests, bodies out its semi-disclosures. So that to perceive what has never been perceived before is, in a sort of way, an act of *invention*. It thus happens that an accurate is not always an original observer. Novelties, as such, are almost inaccessible to many persons with exquisite powers of vision for whatever is already known to be within its range.

The late Baron Dembowski was an example of a first-rate observer but slightly endowed for detection; Mr. Burnham, on the other hand, is a born discoverer. The accidents of his career have turned his attention almost exclusively to double stars; and his glance seems to have a compulsive power of turning simple into compound objects by long and intent looking. His Chicago thousand of new pairs are famous; he bids fair to accumulate an equally imposing array at Lick. Nor does he neglect the old in the search for the new. The more exciting is not permitted to exclude what is in many respects the more useful occupation.

Progress in double-star astronomy is absolutely dependent upon remeasurements of the relative positions and distances of known pairs. We can otherwise learn nothing as to the nature of their connection. Inquiries about them can, by this means alone, be pushed through the three successive stages leading up towards complete knowledge. In the first place, it has to be decided whether the stars shift their places perceptibly with reference one to the other. If they are "fixed," but with a common proper motion, then they may safely be set down as physically coupled, although centuries may elapse before the character of their mutual revolutions becomes apparent. In the next place, the nature of relative motions, where they exist, has to be ascertained. Should they prove to be rectilinear, that fact alone overthrows the possibility of any real connection between the stars. Each pursues its way independently of the other. Finally, in the interesting cases in which curvilinear motion shows itself, persistent micrometrical measures are required to determine the shape and period of the orbit traced out.

Yet the majority of these objects receive little or no attention. This is in part due to their great numbers. About 12,000 double stars—using the term in the widest sense—are now known; nearly 5000 are in really close conjunction—so close, in some 1400 instances, as to render the chances of accidental juxtaposition all but evanescent. Only between fifty and sixty stellar orbits have, however, as yet been computed, and many of them from most inadequate data. The truth is, that this branch of work wants organizing. It is too vast and too important to be abandoned to the capricious incursions of irresponsible amateurs, whose industry is often wasted by being misapplied. There ought, nevertheless, to be little difficulty in distributing the observational resources available as advantageously as possible by the intervention of some recognized authority, a central repository being at the same time constituted whence computers could obtain on demand the materials needed for the investigation of particular systems. The tasks of stellar astronomy are so multitudinous as imperatively to demand combination for their effectual treatment.

Discovery, meanwhile, must advance as it can. It is far from desirable that it should remain stationary. Although our acquaintance among double stars is already embarrassingly large, we cannot refuse to extend it. Every addition to it, indeed, is, for a variety of reasons, to be welcomed.

Information on the general subject of stellar compositeness can only be gained by continually widening the area of research. The comparative frequency of its occurrence can thus only be estimated. Struve found one in forty of 120,000 stars examined by him down to 1827 to be compound; but the proportion was naturally higher for the brighter stars, as being in general much nearer the earth, and consequently of more facile optical separation. Every twenty-fifth star in Piazzi's Catalogue, every eleventh in Flamsteed's, proved accordingly to have a companion within less than 32″. But the process of dividing stars has since made such strides as to show that the real preponderance of single over double ones must be much smaller than these numbers indicate. Perhaps, indeed, no star can be called absolutely single. Between a small companion sun and a large planet in its self-luminous stage it is not easy to establish a distinction. The star we know best may not always have been, in its "surpassing glory," so undeniably solitary as it now is. Jupiter, if it ever shone with anything like stellar lustre, would have constituted with it a fine unequal pair such as are plentifully exemplified in our catalogues.

The distribution of double stars is characterized by a somewhat irregular condensation towards the Milky Way. They abound in Cygnus and Lyra, are scanty in Cassiopeia and Cepheus; while Struve met with rich regions where lucid stars are few, in Auriga, Telescopium, and Lynx. Burnham, however, could detect no marked local preferences among his numerous pairs. Sir John Herschel was struck with the paucity of close doubles in the southern hemisphere; but no searching scrutiny has yet been carried out there with modern instruments.

The curious tendency of stars already in close association to split up still further when sufficiently powerful means are brought to bear upon them, has been strongly accentuated by Mr. Burnham's investigations. Primaries with double satellites, such as Rigel, or satellites with double primaries, such as ξ and β Scorpii, swarm on his lists. A fresh instance of the former kind is ζ Piscium (Σ 100), registered by Struve as somewhat widely double, but found to be triple last autumn with the Lick twelve-inch achromatic. The satellite of Struve's companion, at an interval of less than one second from it, is of the eleventh magnitude. The bright stars are estimated by Burnham as of sixth and eighth, but were photometrically determined at Harvard as of 5·4 and 6·4 magnitudes; and Webb thought that the chief of the pair occasionally rose to the fourth rank of lustre. A presumption is thus afforded that both fluctuate in light. Their spectrum, like that of most variable double stars, is of the Sirian type; and their real fellowship is made manifest by a community of proper motion. We have here, then, a genuine ternary system.

Aldebaran is the centre of a mixed group. A small star at 30″ detected by Mr. Burnham at Chicago on October 31, 1877, was described by him as making with the ruddy bright star, a pair resembling Mars and his outer satellite (*Astr. Nach.*, No. 2189). A drift together through space

is probable, Mr. Burnham's remeasurements after eleven years indicating relative fixity, notwithstanding Aldebaran's appreciable advance in the meantime. A more remote companion, however, discovered by Herschel in 1781, is certainly optical, and has been shown at Lick to be double (*ibid.*, No. 2875). Most likely it forms part of the cluster of the Hyades, upon which Aldebaran is casually projected.

The division of the leading member of the group known as σ Orionis illustrates Struve's remark that multiple stars are intermediate between double stars and clusters. Herschel saw it as doubly triple, one set being much fainter than the other. Each proved, under Struve's and Barlow's scrutiny, quadruple, with two very small stars between; while the chief of the decuple assemblage has been resolved at Lick into an excessively close pair, recalling the case of Sir J. Herschel's quintuple star 45 Leporis, broken up into *nine* components by Burnham in 1874. No relative, and scarcely any absolute motion is perceptible among the constituents of σ Orionis; but one of them, called "ashen" by Struve, "grape-red" by Webb, is perhaps variable in colour.

The "Pointer" next the Pole, α Ursæ Majoris, has so far been seen as double only with the giant telescope of Mount Hamilton. The extreme difficulty of the pair arises from the disparity of light between its members, the eleventh magnitude satellite at 0''·83 being almost swallowed up in the glare of its brilliant primary. This disparity, too, throws some shadow of doubt on the reality of the connection, since the supply of small stars for the occupation of chance positions is of course vastly greater than of large. The similar, but more distant companion of γ Cassiopeiæ (at 2''·18) also recently discovered at Lick, is hence not unlikely to prove merely optical, the Milky Way, in which this pair occurs, being pre-eminently rich in such objects; and the presumption is still smaller that a fourteenth magnitude neighbour of θ Cygni owns a genuine allegiance. But here, as Mr. Burnham points out, the proper motion of the larger star will speedily decide (*Astr. Nach.*, No. 2912.) There can, on the other hand, be no hesitation in admitting that η Ophiuchi, resolved last spring by the same indefatigable observer into two nearly equal components, at 0''·35, constitutes a physical system, and one in which rapid movements may be looked for. The stars evidently travel together, else they should have been, through the effects of a proper motion of one second of arc in ten years, so far apart a little time back that they could not possibly have escaped separate discernment. Their relation to the Milky Way is picturesque, and has been thought to be significant. "Situated at the extreme northern and pointed extremity of a luminous elongated patch of milky light," Mr. Gore remarks, η Ophiuchi "looks as if it were drawing the nebulous matter after it like the tail of a comet" (*Journal Liverpool Astr. Society*, vol. vii. p. 178). But we may safely regard the appearance as illusory.

Some of Mr. Burnham's measures of known doubles also supply results of interest. Thus, the duplex, sea-green companion of γ Andromedæ can now barely be "elongated" with a magnifying power of 2700 on the great refractor. Yet, so lately as 1881, the two stars could be distinguished with eight inches of aperture. The unequal pair, 99 Herculis, discovered by Alvan Clark in 1859, is even more recalcitrant. No amount of optical constraint can now extract from it the slightest indication of duplicity. Since 1878, 85 Pegasi has traversed 213° of its orbit; and Mr. Schaeberle's new elements, embodying the Lick data, give it a period of 22½ years, and oblige us (on the dubious assumption that Brünnow's small parallax can be depended upon) to ascribe a mass to the system eleven times the solar, the components revolving at nearly eighteen times the distance of the earth from the sun. The sun and Jupiter, if of equal *areal* lustre, would present, at half the supposed distance of 85 Pegasi, just its telescopic aspect.

Like 85 Pegasi, δ Equulei is optically triple, while physically double, the companionship of Struve's more distant attendant being in each case temporary and accidental. The bright star of δ Equulei was divided by O. Struve in 1852, and the pair soon proved to be in exceptionally rapid motion. They constitute, in fact, the swiftest binary system yet known. Glasenapp's period, nevertheless, of 11½ years is evidently too short. The Lick measures show the star to be lagging slightly behind its predicted place.

The investigation of stellar orbits has scarcely yet emerged from a tentative stage. Its results are for the most part loose approximations, largely open to future correction. There are very few stars of which the period is known within a few years; there are perhaps two—42 Comæ and ξ Ursæ—of which it is known within a few months. This is due to no lack of skill or diligence in the computers, but solely to the deficiencies, both in quality and quantity, of the materials at their command. Very small errors become enormous when they affect the relative situations of objects divided by a mere *hair-breadth* of sky; and there is no branch of astronomy in which "personality" has played a more conspicuous or a more vexatious part than in double-star measurements. This at least is abolished by photography; which has, however, as yet proved applicable only to a limited class of coupled stars. With the extension of its powers to all, a new era in the knowledge of stellar revolutions may be expected to open.

A. M. CLERKE.

GEOLOGICAL EXCURSION TO THE ACTIVE AND EXTINCT VOLCANOES OF SOUTHERN ITALY.

THE excursion of geologists to the volcanic regions of South Italy came to a very satisfactory conclusion. We have already referred to the first part of the excursion to the Lipari Islands, and the interesting state of activity in which the volcanoes of Vulcano and Stromboli were found to be in. On leaving those islands the party proceeded to examine the Val di Bove, the Cyclopean Islands, the slopes of Etna with its numerous parasitic cones and lava streams, and the central crater itself. The Italian Minister of Public Instruction allowed the party to sleep in the observatory near the mountain summit, and although the weather was rough and misty, about half the party were able to get a good view of the crater, which is now in a solfataric condition. The geologists had also the advantage of becoming acquainted with the mud volcanoes of Paterno. In this part of the excursion the party had the valuble help of Prof. O. Silvestri, to whom Dr. Johnston-Lavis handed over the direction at Etna, although still acting as general director and interpreting Prof. Silvestri's demonstrations. All along the journey the party were *fêted* by the prefect of the province and the mayors of the different communes, and found invaluable hospitality in the splendid villa of the Marquis Favara at Biancavilla. The second fortnight of the excursion was spent at Naples and its vicinity, under the direction of Dr. Johnston-Lavis, aided for the sedimentary rocks by Prof. Bassani of the University of Naples. Although the weather was not so favourable as in Sicily, the delay only amounted to two days. Many thanks are due to the mayor of Naples for his hospitality in providing for the party a splendid steam yacht for their visit to Capri and Ischia, so affording very greatly increased facilities for their excursions. The members gave a day to the examination of the reservoirs and other works connected with the new and most perfect and purest town water supply in Europe, as well as the new drainage works and destruction of the old town of Naples. Although the visit to the crater of Vesuvius had to be delayed for upwards of ten days for suitable weather,

the party had the good fortune to see the volcano in great perfection. There existed at the time of the visit four concentric crater rings and two main vents ejecting red-hot lava cakes, which the geologists were able to approach within ten yards, after which they descended some distance on the slopes of the great cone to a small lava stream issuing from its sides, at which various experiments were performed. The director, who has visited the crater over sixty times, remarked that he had never but once seen it to greater perfection.

The numerous volcanoes of the Phlegrean fields were examined, and most of those present expressed their satisfaction at the many important lessons to be learnt from them. At Pompeii the members had the valuable direction of Dr. A. Sambon for the archæological part, whilst Dr. Johnston-Lavis devoted himself only to explaining the phenomena and materials associated with the destruction of the buried cities.

After Naples the party examined on their way northwards the volcano of Roccamonfina, under the direction of Dr. Johnston-Lavis, and Monte Cassino under that of Prof. Bassani of Naples. The Lyceum at Sessa Aurunca was kindly lent by the commune to accommodate the members during their night's stay on their way over the mountain, a sumptuous dinner being provided by the municipality. The carriages the next day were offered by the province of Terra di Lavoro, and after the ascent had been made of the central cone (Mount Santa Croce) a lunch not less sumptuous than the dinner of the preceding evening was given by the town of Roccamonfina.

The next day was devoted to Monte Cassino, its manuscript and art treasures, as well as the Cretaceous limestones constituting the mountain upon which it is built. Prof. Bassani acted as geological director.

At Rome the party examined the concentric craters, parasitic cones, crater lakes, lava streams of the Alban volcano, also the fossiliferous Pliocene beds capped by volcanic deposits close to the Eternal City. The lower Mesozoic limestones, the travertine, the sulphur springs, and all the other points of geological interest of the Campagna Romana were visited.

As directors of the excursions around Rome may be mentioned Profs. Mele, Portis, and Strüver. Signor Zezi (secretary of the Italian Geological Survey), Signors Demarchi, Clerici, Tellini, and Prof. Lanciani kindly undertook the archæological demonstrations which acted as dessert to the rich geological repast.

The official excursions terminated on October 28, with the trip to Tivoli, although a number of geologists remained to visit the sights of Rome. In the evening a dinner was offered to Dr. Johnston-Lavis, Mr. L. Sambon, and the Roman directors. The thanks of the party were offered to the Minister of Public Instruction, Prefects and Mayors, and private individuals, who had done so much to facilitate the progress, through often almost inaccessible districts, for a large party.

Special votes of thanks were proposed to the different Italian geologists who had kindly offered their services in directing the party through their districts, and lastly to Dr. Johnston-Lavis for originating this new departure in scientific excursions, as well as acting not only as director in his own districts, but interpreting and organizing during the whole excursion, and to Mr. L. Sambon for his administrative skill, his attainments in different branches of science, which added so much to the success and comfort of over forty English geologists, not to speak of the numerous Italians who from time to time joined.

REMARKABLE HAILSTONES.

On p. 43 of the present volume of NATURE the following extract is given from a paper by Prof. Houston in the Journal of the Franklin Institute :—"On some of the hailstones, though not on the majority of them, well-marked crystals of clear transparent ice projected from their outer surfaces for distances ranging from $\frac{1}{8}$ to $\frac{1}{4}$ of an inch. These crystals, as well as I could observe from

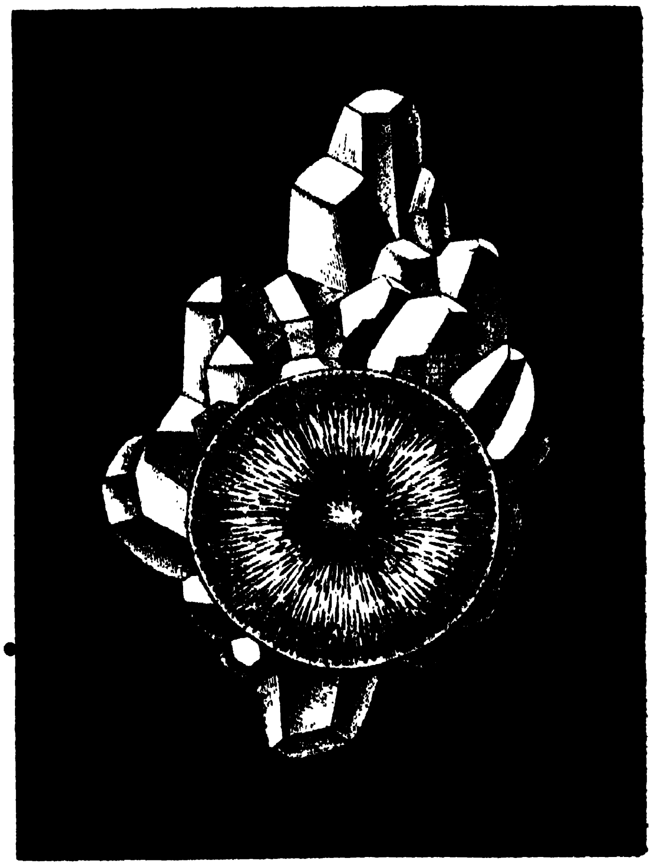

Fig. 1.

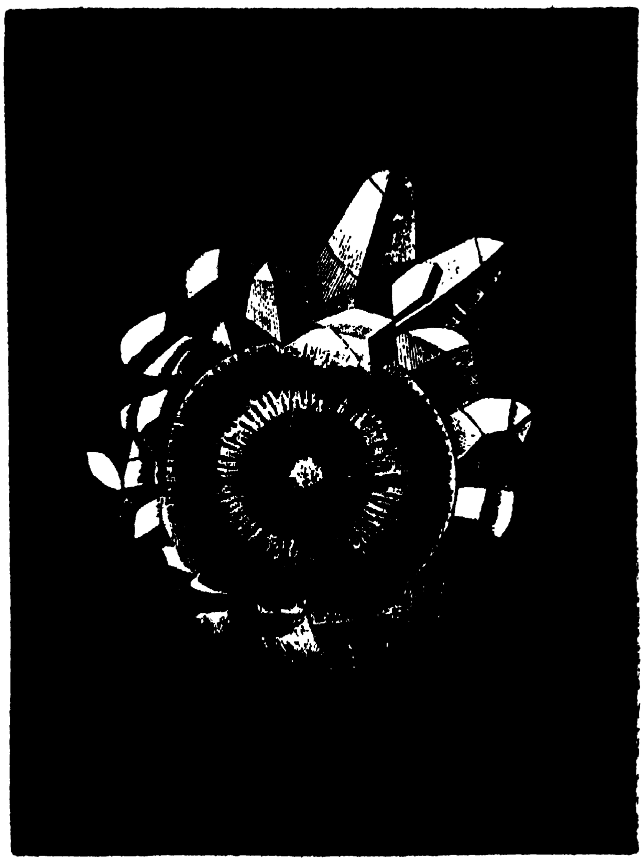

Fig. 2.

the evanescent nature of the material, were hexagonal prisms with clearly cut terminal facets. They resembled the projecting crystals that form so common a lining in

geodic masses, in which they have formed by gradual crystallization from the mother-liquor. They differed, however, of course, in being on the outer surface of the spherules."

It is evident from Prof. Houston's paper that this peculiar form of hail was unknown to him, and, as it must also have been unknown to many who have propounded theories as to the formation of hail which will not account for it, I think that a service may be rendered to meteorology by the reproduction of three of the exquisite lithographs of this form of hail given in Prof. Abich's paper, "Ueber krystallinischen Hagel im Thrialethischen gebirge," published at Tiflis in 1871. The hailstones represented in Figs. 1–3 all fell on June 9 (21), 1867, at Bjeloi Kliutsch, a village about twenty miles south-west of Tiflis,

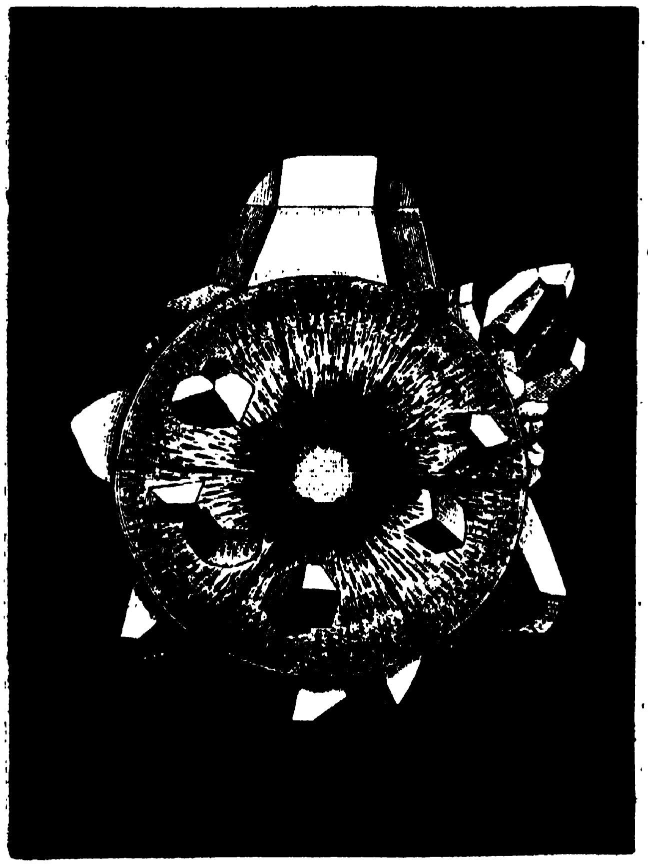

Fig. 3.

and 12,425 feet above sea-level (lat. 41° 33′ N., long. 44° 30′ E.).

Theories of the formation of hail are almost innumerable. I was reading a pamphlet not long since which contained summaries of, I think, twenty-three theories. Some—like Prof. Schwedoff's, that hailstones come from interplanetary space (Brit. Ass. Report, Southampton, 1882, p. 458)—are very droll; but the subject is a very difficult one, and one upon which I do not know of a single good treatise in our language. Possibly, the reproduction of these figures may induce someone to prepare an exhaustive memoir. I could place a large amount of historical and theoretical material at the disposal of any competent person who would undertake the preparation of such a work, it being quite impossible for me to do it myself.

G. J. SYMONS.

NOTES.

AT a largely attended meeting in Edinburgh on Tuesday, Dec. 3, Sir Douglas Maclagan in the chair, it was resolved that Mr. Geo. Reid, R.S.A., should be commissioned to paint a portrait of Prof. P. G. Tait, to be placed permanently in the rooms of the Royal Society of Edinburgh. A committee was appointed to carry out the resolution, including, among others, Mr. John Murray (*Challenger* Expedition), Convener; Mr. Gillies Smith, Hon. Treasurer; Lord President Inglis, Lord Kingsburgh, Lord Maclaren, Sir William Thomson, Sir Arthur Mitchell, Prof. Robertson Smith, Prof. Chiene, Dr. Alexander Buchan, Mr. Robert Cox, and Mr. William Peddie. It was proposed that an etched engraving of the portrait be prepared for distribution among the subscribers, the plate to be destroyed after the required number of copies have been thrown off. It was further resolved that all the Fellows of the Royal Society of Edinburgh, the Professor's old pupils, and others, be afforded an opportunity of taking part in this public recognitition of Prof. Tait's eminent services to science.

ITALY, France, and the United States of America were represented in the elections to foreign membership of the Royal Society on Thursday last. Prof. Stanislao Cannizzaro, of Rome, was elected on the ground of his researches on molecular and atomic weights; Prof. Chauveau, of Paris, for his researches on the mechanism of the circulation, animal heat, nutrition, and the pathology of infectious diseases; and Prof. Rowland, of Baltimore, for his determination in absolute measure of the magnetic susceptibilities of iron, nickel, and cobalt; for his accurate measurements of fundamental physical constants; for the experimental proof of the electro-magnetic effect of electric convection; for the theory and construction of curved diffraction-gratings of very great dispersive power; and for the effectual aid which he has given to the progress of physics in America and other countries.

ADMIRAL MOUCHEZ and MM. Janssen and Perrotin, head astronomers of the Observatories of Paris, Meudon, and Nice, were raised, in November, to the grade of Officer of the Order of the Rose of Brazil, and MM. Frassenet, Paul, and Prosper Henry, admitted to knighthood in the same order. The Paris Correspondent of the *Daily News* says that the diplomas securing to them these distinctions were the last official documents signed by Dom Pedro. He asked his secretary to add a personal compliment to each of the astronomers with whom he was personally acquainted.

SOME time ago we announced that a Physical Society was about to be formed in Liverpool. This has now been done, and we are glad to learn that the new Society begins its career under most favourable conditions. The meeting at which it was constituted was well attended, and displayed much interest in the scheme. Nearly ninety names were at once handed in to the secretary, Mr. T. Tarleton, for membership. Prof. Oliver Lodge, F.R.S., was appointed President. The next meeting will be held in the Physics Theatre, University College, Liverpool, on Monday, the 16th inst., at 8 o'clock, when the President will deliver his inaugural address.

DR. JOHN G. MCKENDRICK, F.R.S., Professor of Physiology in the University of Glasgow, has been elected President of the Philosophical Society of Glasgow.

PROF. LESQUEREUX, the eminent American bryologist and palæontologist, died in his house at Columbus, Ohio, on October 25, at the age of nearly eighty-nine years.

WE regret to learn from a memoir that has been sent to us by Prof. Barboza du Bocage, that Señor José Augusto de Souza died recently at Lisbon, where he was Curator of the Zoological Department in the Museum. He was the author of some useful memoirs on African birds, and is best known for his Catalogue of the *Accipitres*, *Columbæ*, and *Gallinæ* in the Lisbon Museum.

THE fifth of the series of "One Man" Photographic Exhibitions at the Camera Club will be open for private and press

view on Monday, December 16, at 8 p.m., and on and after Tuesday, December 17, it will be open to visitors on presentation of card. The Exhibition will consist of pictures by the late Mr. O. G. Rejlander, and a selection from over 200 of his famous figure and *genre* studies will be shown. The pictures will be on view for about six weeks.

ON November 21 the American Philosophical Society, Philadelphia, celebrated the hundredth anniversary of its first occupation of its present hall. The banquet was a great success. The following were the toasts:—"The language of Science and Philosophy is universal, but adopts various dialectic forms to diffuse knowledge," proposed by Prof. John W. Mallet, representative from the Royal Society of London; "Our kindred Societies in every clime," proposed by Prof. Joseph Lovering, President of the American Academy of Arts and Sciences; "All research into the Book of Nature has not discovered an erratum," proposed by Sir Daniel Wilson, President of the University of Toronto; "The successful pursuit of Science expunges error—it never antagonizes truth," proposed by the Hon. Lyon G. Tyler, President of William and Mary College; "Mental Analysis is the efficient solvent of many difficulties in Science and Philosophy," proposed by the Rev. Dr. Charles W. Shields, Princeton College; and "The labours and achievements of great teachers in Science and Philosophy live after them—these are their monuments," proposed by the Right Rev. Dr. John J. Keane, President of the Catholic University of America.

DR. PAX, of Breslau, has been appointed Curator of the Botanic Garden in Berlin; Mr. D. G. Fairchild, Assistant in the section of Vegetable Pathology in the United States Department of Agriculture; Dr. H. Dingler, Professor of Botany in the Forest Academy of Aschaffenburg; Dr. F. Noll, Professor of Botany in the University of Bonn; and Dr. N. Wille, of Stockholm, Lecturer on Botany at the Royal Agricultural Institution at Aas, near Christiania.

PROF. BORNMÜLLER, Director of the Botanic Garden at Belgrade, has started on a twelve months' botanical tour through Asia Minor. Beginning at Amasia, he will travel through the country between the courses of the Kisil-Irmak and Euphrates, southward to the completely unexplored mountains of Ak-dagh. The *Botanical Gazette* says that this country has only once been explored, thirty-five years ago, by the Russian botanist Wiedemann. According to the same authority, Prof. Bornmüller is a young and very successful explorer, with a great deal of experience, especially from his long journey in 1886, through Dalmatia, Monte Negro, Greece, Turkey, East Bulgaria, and Asia Minor. His original collection will be transferred to Weimar, where it will be carefully gone through by Prof. Hausknecht.

THE "mountain laurel," or *Kalmia*, and the Indian corn, are suggested in American papers as national flowers for the United States.

IN the December number of the *Kew Bulletin* Mr. Thiselton Dyer explains that for some years, when it has been necessary to find space in the Palm House at Kew for the development of new and interesting species of palms, he has not hesitated to transfer to the Temperate House plants which he thought would probably endure a lower temperature. The experiment has been most successful, many of the plants luxuriating in the change. Anxious to obtain further information as to cool cultivation of tropical and sub-tropical plants, Mr. Dyer lately applied for leave to send Mr. Watson, assistant curator at Kew, to the south of France to report on what he might be able to observe. Permission was given; and Mr. Dyer's statement is followed by a series of valuable and interesting notes in which Mr. Watson sums up the results of his mission. His journey took place in the latter part of October. He had a fortnight at his disposal, and during that time he visited as many gardens as possible between Hyères and Mentone. One of the most interesting of the gardens visited was a branch establishment, at Hyères, of the Société d'Acclimatation, Paris. Here a good deal of experimental gardening is practised, plants of all kinds being planted and tested as to their hardiness, &c. Mr. Watson says that while he was inspecting these gardens the idea was suggested "that a well-managed botanical station, devoted chiefly to experimental testing, proving, and breeding operations amongst plants, would, if established in some such favoured locality as Hyères, be capable of much valuable work."

THE following are the lecture arrangements at the Royal Institution, so far as they relate to science, before Easter:—Prof. A. W. Rücker, six Christmas lectures to juveniles on electricity; Prof. G. J. Romanes, ten lectures on the post-Darwinian period; Mr. Frederick Niecks, four lectures on the early developments of the forms of instrumental music (with musical illustrations); Prof. Flower, three lectures on the natural history of the horse and of its extinct and existing allies; the Right Hon. Lord Rayleigh, seven lectures on electricity and magnetism. The Friday evening meetings will begin on January 24, when a discourse will be given by Prof. Dewar on the scientific work of Joule. Succeeding discourses will probably be given by Sir Frederick Abel, Mr. Henry B. Wheatley, Prof. J. A. Fleming, Mr. Shelford Bidwell, Prof. C. Hubert H. Parry, Mr. Francis Gotch, Prof. T. E. Thorpe, Prof. G. F. Fitzgerald, the Right Hon. Lord Rayleigh, and other gentlemen.

MESSRS. MACMILLAN AND CO. will shortly publish the first part of Prof. Eimer's work on "Organic Evolution as the Result of the Inheritance of Acquired Characters according to the Laws of Organic Growth," translated by J. T. Cunningham, M.A., F.R.S.E., late Fellow of University College, Oxford.

MESSRS. BLACKWOOD AND SONS have just published "The Construction of the Wonderful Canon of Logarithms," a translation of "Mirifici Logarithmorum Canonis Constructio," by John Napier, of Merchiston. The work was published in 1619, but is so rare as to be very little known, being only once reprinted in 1620, and never translated. The present translation is by William Rae Macdonald, who also contributes notes and a catalogue of Napier's works.

SLIGHT shocks of earthquake, lasting from five to ten seconds, were felt on Sunday, at Taranto, Foggia, Chieti, Montesaraceno, Agnone, Ancona, and Urbino. At Torremileto, in the province of Foggia, a strong shock is said to have been felt; and a slight shock, followed by a somewhat stronger one, occurred at Naples soon after 6 a.m. On Monday there were seismic disturbances in Dalmatia, Bosnia, and Herzegovina. According to a telegram, through Reuter's Agency, from Vienna, a somewhat severe shock was felt on Monday, at 6.30 a.m., at Knin, Dernis, Sebenico, Trau, Scardona, and Spalato, the direction of the movement being from north-east to south-west. A violent shock, lasting five seconds, occurred at 6.40 at Serajevo, being felt three minutes later at Novi and Krupa also.

AT the ordinary meeting of the Council of the Sanitary Assurance Association, on Monday last, arrangements were completed for a series of lectures during January and February 1890, in the theatre of the College of State Medicine, Great Russell Street. The series will include the following:—Mr. H. Rutherfurd, barrister-at-law, on "House Sanitation from a Householder's Point of View," Sir Joseph Fayrer, F.R.S., in the chair; Prof. T. Roger Smith, on "Household Warming and Ventilation," Sir Douglas Galton, F.R.S., in the chair; Mr. Mark H. Judge, on "The Sanitary Registration of Buildings Bill," Lord Henry Bruce, M.P., in the chair. The object of

the Association being to promote good sanitary arrangements in the houses of all classes of the community, both men and women are invited to these lectures. Discussion is invited.

THE "Fauna of British India," of which we noticed the first volume of fishes last week, is making steady progress. Mr. Eugene Oates will produce the first volume of the birds of India during the present month. The work will be principally founded on the great Hume Collection in the British Museum, and the author of the "Hand-book of the Birds of British Burmah," may be trusted to give a thoroughly good account of the birds of India. Side by side with his three volumes on Indian ornithology, Mr. Oates will also publish a new edition of Mr. A. O. Hume's "Nests and Eggs of Indian Birds," which has long been out of print. For this purpose Mr. Hume has intrusted to Mr. Oates the whole of the material collected by him for a second edition, and there is no doubt that the work will be warmly welcomed by naturalists. Portraits of some of the leading men who have contributed to the history of Indian ornithology will be given in this new edition, and will form an interesting feature of the work.

MR. FRANCIS NICHOLSON, a well-known Manchester ornithologist, is about to issue an English translation of Sundevall's "Tentamen," with a memoir and portrait. This work will be welcome at the present time, when increased attention is being paid to the classification of birds.

MR. SEEBOHM will, we understand, propound his system of arrangement of the class Aves in the January number of the *Ibis*, and the memoir will doubtless be a valuable one, as the author is known to have devoted close study to the subject during the past two years.

MR. A. P. GOODWIN, who was with Sir William McGregor on his recent exploration of Mount Owen Stanley, is about to start on a lecturing tour in America. He was successful in taking several interesting photographs of the country visited by the Expedition, and he paid especial attention to the habits of the Birds of Paradise and the Bower-birds. He has some remarkable sketches of the playing-grounds of some of the latter, notably of *Amblyornis subalaris*, of Sharpe, which rivals in decorative faculty the Gardener Bower-bird (*Amblyornis inornata*) of North-Western New Guinea.

PROF. GIARD has recently discovered a micro-organism which possesses the power of conferring luminosity or phosphorescence upon different crustaceans. This microbe was found in the tissues of *Talitrus*, and is easily cultivated in appropriate media. It soon kills *Talitrus*.

M. LOUBAT, member of the New York Historical Society, has presented the French Academy of Inscriptions with a sum producing 1000 francs per annum; his intention being that a prize of 3000 francs shall be offered every three years for the best printed work concerning the history, geography, archæology, ethnography, linguistics, and numismatics of North America. The first prize will be granted in 1892, and the Academy has decided that the works submitted for consideration shall not relate to matters referring to an earlier date than 1776. The competition will be open to the author of any work on the subject published after July 1, 1889, in any of the following languages: Latin, French, English, Spanish, and Italian. Two copies must be sent to the Secretary of the French Institute before December 31, 1891.

IN the Pacific Coast region there are now four flourishing colonies of introduced pheasants. Dr. C. Hart Meriam, who refers to the subject in his last Report to the American Agricultural Department, says that the most northerly of these colonies is at the south end of Vancouver Island, near Victoria; the second in Protection Island, in Puget Sound; the third at the junction of the Willamette River with the Columbia; and the fourth in the middle portion of the Willamette Valley. The two latter colonies are now separated by so narrow a strip of territory that they will doubtless become united during the next few years. All the pheasants of the three colonies last mentioned appear to have been imported from China by Judge O. N. Denny.

THE American Agricultural Department has been making careful inquiry as to the food of crows; and the result, as set forth in a Report by Mr. Walter B. Barrows, is likely to surprise those who have always contended that these birds do very much more good than harm. It is not disputed that they destroy injurious insects, that they are enemies of mice and other rodents, and that they are occasionally valuable as scavengers; but these services are slight in comparison with the mischief for which they are responsible. The injury done by them to Indian corn, wheat, rye, oats, and other cereals is enormous. According to one observer, the crow eats corn "from ten minutes after planting until the blades are three inches high;" and more than a score of other observers testify that he not only pulls up the young plants, but digs up the newly sown seed. His depredations extend to potatoes, sweet potatoes, beans, pea-nuts, cherries, strawberries, raspberries, and blackberries; and he widely distributes certain poisonous plants, the seeds of which are improved rather than impaired by passage through his digestive organs. As if all this were not enough, it is shown that the crow eats beneficial insects, and that he makes himself a most formidable nuisance by destroying the eggs and young both of domesticated fowls and wild birds.

TWO new seismoscopes, made by Brassart Brothers, of Rome, and adopted at the Italian meteorological stations, are described in the *Rivista Scientifico-Industriale* of October 15. They are of a very simple nature, the one consisting merely of an iron rod, about 5 inches long, leaning slightly against an adjustable screw support near its middle, and with its lower pointed end in a cup. When a shock or tremor occurs, the rod falls away from its support and is caught by a fixed metallic ring, making electric contact and ringing a bell. In the other instrument, the ring is connected with a hinged lever arrangement, which stops the mechanism of a timepiece, showing when the shock occurred.

THE National Association for the Promotion of Technical and Secondary Education has issued an excellent Report on the existing facilities for technical and scientific instruction in England and Wales As Mr. Acland and Mr. Llewellyn Smith explain in a prefatory note, the Report is not intended so much for experts as for those who wish to obtain, without consulting many Blue-books and other official documents, some trustworthy information as to what is being done. The facts have been arranged with the utmost care, and the work ought to be of considerable service in helping to show "what are the gaps in our educational system that must be filled, and how great is the need for the re-organization and improvement of existing agencies."

THE Annual Report of the Manchester Literary and Philosophical Society, published in vol. ii., 4th series, of the Proceedings, shows a marked improvement in the financial condition of the Society, the membership being only one less than at the corresponding period last year. The volume contains many papers and abstracts of papers of varying interest. There is a long paper on "*Hymenoptera Orientalis*" by Mr. Cameron, giving descriptions of the various species, their habits and localities, and references to the literature of the subject. Dr. A. Hodgkinson communicates an interesting paper on the "Physical Cause of Colour in Natural and Artificial Bodies," recording experiments which tend to show whether the colour is produced by a

structure of thin plates, or one of fine lines. There are two papers on leaves from the cutting of the Ship Canal, one giving a general description, and the other, by Dr. Schunck, F.R.S. showing that the green colouring-matter, which has proved to be so permanent, is due to a modified form of chlorophyll; spectroscopic examination of the colouring-matter showed it to be identical with that produced by the action of dilute hydrochloric acid on ordinary chlorophyll.

THE Middlesex Natural History and Science Society has issued a volume containing its Transactions during the session 1888-89. The volume opens with an interesting Presidential address by Prof. Flower, on the Natural History Museum, Cromwell Road, and some recent additions thereto. Mr. E. M. Nelson has an illustrated paper on diatom structure; and Mr. J. A. Brown contributes a paper, also illustrated, on working sites and inhabited land surfaces of the Palæolithic period in the Thames Valley.

THE fourth volume of "Blackie's Modern Cyclopædia" has been issued. It begins with the word "fire" and ends with "Ilorin." The work, as we have said on former occasions, is admirably edited by Dr. C. Annandale. The articles are necessarily brief; but, so far as we have been able to test them, they are clear and accurate. There is no falling off in the present volume.

MESSRS. WARD, LOCK, AND CO., have added to their "Minerva Library of Famous Books" a reprint of Dr. A. R. Wallace's fascinating "Narrative of Travels on the Amazon and Rio Negro." A biographical sketch of the author is contributed by Mr. G. T. Bettany, the editor of the series; and the volume includes a portrait of Dr. Wallace, a map, and full-page illustrations.

HAZELL'S Annual for 1890—the fifth issue—has been published. It is edited by Mr. E. D. Price. An immense quantity of information, alphabetically arranged, has been packed into this useful volume. Many articles which the editor describes as "new and important" have been inserted in the present issue.

A SCIENCE CLUB has been formed among the students of the University of St. Andrews for the purpose of developing the interest already taken in scientific pursuits. Prof. W. C. McIntosh, F.R.S., has been elected Hon. President for the session 1889-90.

ANOTHER important paper by M. Henri Moissan upon the perfected mode of preparation and upon the density of fluorine, is contributed to the current number of the *Comptes rendus*. Since the appearance of his paper of two years ago, M. Moissan has employed an electrolysis apparatus of much larger size, and has added to it an accessory apparatus by means of which the gas may be obtained quite free from vapour of hydrofluoric acid, which, as described in NATURE last week, is the cause of the destructive action upon platinum. The platinum U-tube of the new apparatus has a capacity of 160 c.c., and contains during the electrolysis 100 c.c. of hydrofluoric acid. The exit tube at the positive side, from which the fluorine is liberated, is continued into a small platinum spiral condenser immersed in a bath of methyl chloride at -50° C., where all but the last trace of hydrofluoric acid is retained. From this the gas is led through two platinum tubes filled with fragments of sodium fluoride, a salt which combines with hydrofluoric acid with great energy, forming hydrogen sodium fluoride. By these means the fluorine is obtained perfectly pure, and is quite invisible in dry air, no trace of fuming being apparent, as is the case before purification. In order to determine the density of the gas, a couple of ingeniously constructed platinum flasks have been employed. Each of these flasks is closed by a cylindrical stopper also of platinum; to the side of the neck a side tube is attached on a level with the centre of the stopper. Through the stopper an aperture is bored in such a manner that, when the stopper is rotated into a certain position, connection is established between the interior of the flask and the side tube. A vertical tube also passes through the stopper and penetrates to near the bottom of the flask; this tube is also closed at its upper end by means of a platinum stopper. The stoppers are finely polished and adjusted with great care. Each flask weighs about 70 grams and has a capacity of about 100 c.c. In the density determinations the two flasks were counterpoised on the two pans of the balance. One of them was then filled with pure dry nitrogen gas, which was subsequently displaced by the pure fluorine, the electrolysis apparatus being connected with the upper end of the vertical tube of the density flask by means of flexible platinum tubing. The fluorine was allowed to pass through the apparatus for five minutes after cold silicon was readily ignited by the gas issuing from the side exit tube. The stopper of the flask was then rotated through half a revolution, so as to completely shut off the exit tube, and the stopper of the vertical tube replaced. The flask was again weighed against the other flask containing air, and the difference of weight noted. The amount of residual nitrogen was estimated by opening the stopper of the vertical tube under water, when the fluorine instantly decomposed an equivalent of water, liberating oxygen and forming hydrofluoric acid. The mixture of oxygen and the residual nitrogen was then collected, and the oxygen absorbed by pyrogallic acid and potash. Three determinations yielded, for the density of fluorine compared with that of hydrogen, 18·27, 18·26, and 18·33. These values appear to indicate that the number 19, usually taken as representing the atomic weight of fluorine, is slightly too high, and this view is confirmed by the low numbers obtained in former determinations of the density of phosphorus trifluoride.

THE additions to the Zoological Society's Gardens during the past week include a Malayan Bear (*Ursus malayanus* ♀) from Malacca, a Gold Pheasant (*Thaumalea picta* ♀) from China, presented by Captain Bason; a Common Squirrel (*Sciurus vulgaris*), British, presented by Mr. W. Aubrey Chandler; a Mexican Deer (*Cariacus mexicanus* ♂) from Peru, a Grey-breasted Parrakeet (*Bolborhynchus monachus*) from Monte Video, deposited; an American Bison (*Bison americanus* ♂ born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Remarks.

(1) The General Catalogue description of this nebula is as follows:—!!! Bright; very large, irregular figure. According to Tempel, this is a variable nebula, and its spectrum, which has not yet been recorded, will therefore have a special interest. Continued observations may, very probably, give a clue to the origin of the variability.

(2) Dunér classes this with stars of Group II., but states that the spectrum is only feebly developed. Further observations are necessary before it can be placed in position on the "tem-

perature curve." As I have previously pointed out, the "feebly developed" stars of the group are probably either early or late species, as the bands would be weak in either case. If it be an early star, the bands in the blue will be most strongly developed; while, if it be a late star of the group, the bands in the red will be strongest. In the latter case, lines would probably also be seen.

(3) Konkoly classes this with stars of the solar type. As in former stars of this class which have appeared in these columns, observations are required to decide whether the star belongs to Group III. or to Group V. (For criteria, see p. 20.)

(4) This is a star of Group IV., of which observations of the relative intensities of the hydrogen and metallic lines are required, so that the star may be arranged in a line of temperature with others.

(5) This is a star of Group VI., which Dunér describes as having a spectrum consisting of three zones, band 2 being probably also present. Particular attention should be given to the intensity of the band 6 as compared with the others. Other subsidiary bands should also be looked for, as they are seen in several stars of lower magnitude, and it is important that we should know whether their presence is dependent solely upon the brightness of the star, or really indicates a difference in the condition of the star itself. (For notation of bands, see p. 112.)

(6) The maximum of this variable will occur on December 27. The period is 315 days, and the magnitude varies from $< 13\cdot5$ at minimum to 8·6 at maximum. The spectrum has not yet been recorded.

Note.—Some of the comets of which ephemerides have recently appeared in NATURE may possibly be bright enough for spectroscopic examination. It is not likely that, at their present perihelion distances, their temperatures will be very high, so suggestions for comparison spectra may be confined to those suitable for low-temperature comets. The probable sequence of spectra as a comet leaves aphelion is as follows:—(1) The spectrum of a planetary nebula, as in the comets of 1866–67, observed by Dr. Huggins. This consists of a single line in the position of the chief nebula line near λ 500. (2) The low-temperature spectrum of carbon, consisting chiefly of three flutings near λ 483, 519, and 561. (3) The high-temperature spectrum of carbon, consisting mainly of flutings near λ 564, 517, and a group of five flutings extending from 468 to 474. The most convenient comparison to begin with will be the flame of a spirit-lamp, which will give the hot carbon spectrum. If this does not show coincidences with the cometary bands, a comparison with the bright fluting in the spectrum of burning magnesium should be made. This will determine the presence or absence of the chief nebula line. If neither shows coincidences, the positions of the bands relatively to the hot carbon flutings may roughly indicate the presence or absence of cool carbon. As the two less refrangible flutings of cool carbon fall very near to two of hot carbon, the best criterion for cool carbon is the fluting at λ 483, which is about one-third of the distance from the fluting commencing at 474 towards that commencing near 517. Any variation of the form of the least refrangible cometary band from the corresponding carbon fluting should be noted, as this varies with the temperature (see Roy. Soc. Proc., vol. xlv. p. 168). A. FOWLER.

PHOTOMETRIC INTENSITY OF CORONAL LIGHT.—The observations made by Prof. Thorpe during the solar eclipse of 1886 (Phil. Trans., vol. clxxx., p. 363, 1889) show that the diminution in intensity of coronal light at different distances from the sun's limb does not vary according to the law of inverse squares. The following measurements make this apparent:—

Distance in Solar Semi-diameters.	Photometric Intensity. Observed.	Photometric Intensity. Law of Inverse Squares.
1·6	0·066	0·066
2·0	0·053	0·042
2·4	0·043	0·029
2·8	0·034	0·022
3·2	0·026	0·016
3·6	0·021	0·013

The brightness of the brightest measured part of the corona (1·55 solar semi-diameters) was 200 times less bright than that of the surface of the moon, or about 0·06 candle, whilst the furthest spot at 3·66 solar semi-diameters was only 1/800 of the brightness, or 0·015 candle. The results obtained will be useful in comparing the brightness of the corona on this occasion with that of other eclipses, and determining what connection the sun-spot periods have with the coronal phenomena.

CORONA OF JANUARY 1, 1889.—Prof. Tacchini, in the *Atti della R. Accademia dei Lincei* (p. 472), gives a note on the corona as shown in a positive copy, on glass, of one of Mr. Barnard's negatives taken during this eclipse. The corona extends, according to Prof. Tacchini, from +64° to −68° on the west limb of the sun, and from +53° to −68° on the east limb, these being about the limits of the zone of the maximum frequency of protuberances derived from his own observations. Two of the protuberances on the photograph were observed at Rome and at Palermo.

MINOR PLANET (12), VICTORIA.—Dr. Gill has issued the ephemeris of this planet for the opposition of 1889, computed from elements which have been corrected from the observations of 1888.

Observatories co-operating in the meridian observations of Victoria should compare their results with this ephemeris, employing 8″·80 for the solar parallax.

Dr. Auwers has undertaken the discussion of the meridian observations, so the detailed results should be forwarded to him as soon as possible.

COMET SWIFT (*f* 1889, NOVEMBER 17).—The following ephemeris is given by Dr. R. Schorr (*Astr. Nachr.*, No. 2937):—

1889.	R.A. h. m. s.	Decl. ° ′	1889.	R.A. h. m. s.	Decl. ° ′
Dec. 12...	23 47 28 ...	+19 6·7	Dec. 22...	0 19 7 ...	+21 49·4
13...	50 31 ...	19 23·6	23...	22 24 ...	22 4·8
14...	53 36 ...	19 40·4	24...	25 43 ...	22 20·1
15...	56 42 ...	19 57·1	25...	29 2 ...	22 35·2
16...	59 50 ...	20 13·6	26...	32 23 ...	22 50·1
17...	0 2 59 ...	20 29·9	27...	35 44 ...	23 4·8
18...	6 10 ...	20 46·1	28...	39 6 ...	23 19·3
19...	9 22 ...	21 2·2	29...	42 30 ...	23 33·6
20...	12 35 ...	21 18·1	30...	45 54 ...	23 47·7
21...	15 50 ...	21 33·8	31...	49 18 ...	24 1·5

The brightness of the comet = 0·81 (December 12) and 0·57 (December 31), that at discovery being taken as unity.

Comptes rendus, No. 23 (December 2, 1889), contains observations of this comet extending from November 20 to November 27. It is noted that the comet is very feeble and diffuse.

PERIODIC COMETS.—Several short-period comets return to the sun in 1890, and their ephemerides will be furnished as soon as issued. The perihelion passage of Brorsen's comet will occur about February 25, Denning's comet may be expected to return to perihelion in May, and D'Arrest's comet about the third week in September. The orbit of Barnard's comet has not yet been sufficiently defined to enable the date of perihelion passage to be stated.

THE ECLIPSE PARTIES.—The following telegram relating to the eclipse parties has been received:—"*Loanda, December* 7.—The United States corvette *Pensacola*, Captain Arthur R. Yates, with the Solar Eclipse Expedition on board, arrived at St. Paul de Loanda to-day. The voyage down was very smooth, with delightful sailing. The astronomers were at work on the instruments all the way, and are all ready for the eclipse. The time is now so short that it is inadvisable to attempt to take the party and all their instruments inland, so the Expedition will locate at Cape Ledo immediately, and send one or two branch parties inland, with such instruments as are not bulky or heavy, and can quickly be set up and adjusted. The European eclipse observers are beginning to arrive here. Mr. Taylor, of the Royal Astronomical Society, London, has already arrived with a small outfit of apparatus. None of the French or German astronomers are yet here. Cape Ledo turns out to be in every way the most favourable point for locating the American Expedition. Not only are the meteorological conditions likely to be better, but the party can live for the most part on the *Pensacola*, as she will lie at a safe anchorage near the shore. The health of the members of the party is thus insured. The eclipse is several seconds longer there than at Muxima, and chances for clear afternoon skies appear to be rather better. If nothing is heard from the Expedition for the next few days, it may either be taken that the Eclipse Station is finally located at Cape Ledo, or that the semi-cannibal Quissamas have cleared out the whole Expedition."

RECENT INDIAN SURVEYS.

THE "Statement exhibiting the Moral and Material Progress and Condition of India," recently issued, devotes, as usual, a section to the survey work of the past year, of

which the following is a summary. The work of the Survey of India is divided under five heads, namely:—(1) Trigonometrical Survey, (2) Topographical Survey, (3) Cadastral Survey, (4) Special Surveys and Explorations, (5) Map Production.

Trigonometrical.—Out of twenty-six survey parties employed during the year, only one was engaged on trigonometrical work. It carried secondary triangulation for 370 miles along the Coromandel coast as far as the Tanjore District; the work is intended as a basis for marine survey operations. Some triangulation in extension of the great Indian triangles had to be undertaken in Baluchistan as a basis for topographical maps there.

Topographical.—The number of parties engaged in this work was reduced from eight to six, and 15,673 square miles of topographical survey were accomplished, which included 934 square miles of survey in the Southern Mahratta country, the same party doing a quantity of detached forest survey in the valuable teak forests of Kanara; 1085 square miles of topographical work in Guzerat, besides 285 square miles of detailed forest survey in the jungles of Thana and Nasik. Parties 15 and 16 continued the Baluchistan survey, accomplishing in all 11,977 square miles. The cold and snow in winter, as well as the difficulty in getting supplies, were extremely trying to the parties. 977 square miles were surveyed in the Himalayan districts of Kangra, Simla, and the native States pertaining to those districts; 4535 square miles of triangulation and 1284 square miles of topographical survey in the Madura district and the States of Travancore and Cochin of South India. The cost of the Himalayan work and of the Baluchistan surveys was considerably cheaper per square mile than in the previous year.

Forest Surveys.—Two half-parties of the Topographical Survey did fresh work, as above stated, in Bombay. Ground was broken in the forests near Hoskungabad of the Central Provinces; but in the first year, on account of climatic difficulties and the ruggedness of the country, the out-turn of work was small. 343 square miles of forest survey were effected in the forests of the Prome and Thayetmyo districts of Lower Burmah. In Gorakpur of the North-West Provinces, and in Orissa, surveys of certain forest reserves were made by cadastral parties working in the neighbourhood. The whole area of forest surveys accomplished by all these parties during the year was 893 square miles.

Geodetic.—Telegraphic longitude operations were resumed, and seven arcs of longitude were measured between trigonometrical stations in Southern India. The season's observations tend strongly to confirm previous evidence that on the coast of India there is a perceptible deviation of the plum-line towards the ocean.

Tidal and Levelling Operations.—The recording of tidal curves by self-registering tide-gauges, their reduction, and the publication of tide-tables, were continued at eighteen stations, of which seven are permanent, and eleven are temporary for five years. The registrations of tides were satisfactory, and there were few failures. So far as predictions of high water were concerned, 98 per cent. of the entries in the tables were correct within 8 inches of actual heights at open coast stations, and 69 per cent. at riverain stations, while as to time of high water, 56 and 71 per cent. respectively of the entries were correct within fifteen minutes. Levelling operations were prosecuted from Madras to Vizagapatam, at False Point, to connect the Marine Survey beach marks with the main line of level, and from Chinsurah to Nuddea, along the right bank of the Hooghly. There were 597 miles of double levelling accomplished. In Upper Burmah, survey parties or surveyors accompanied the columns which marched through the northern Shan States, the southern Shan States, and the columns that operated in the Yaw country, the Chindwan Valley, and the Mogoung district. Triangulation was carried over 23,274 square miles, and 20,786 square miles of hitherto unknown country were mapped on a scale of four miles to the inch, of which 7605 belonged to the Shan States. North-east from Mandalay, the survey was carried as far as the Kanlow ferry, on the Salween River, a place on the old caravan road between Burmah and China. A large scale map was made of the Ruby Mines tract, showing the sites of all ruby workings. Surveyors accompanied an exploring expedition from the Assam Valley, across the Patkoi ranges, into the Hukong Valley of Upper Burmah, and surveyed two practical passes through the Patkoi hills. A good map of the Black Mountain country was prepared on observations and surveys taken by officers deputed with the Hazara field force. The hill country of Western Nepal has been observed and mapped, and a compilation of recent observations by explorers in Tibet and Bhutan will shortly be published.

Marine Survey.—The survey-vessel *Investigator* and two boat parties were employed on marine surveys throughout the open season, the staff being employed in the chart office during the monsoon months. The *Investigator* accomplished 4630 miles, and the boat parties 1542 miles of soundings. Among the results of the year's work were soundings round the approaches to Madras, whereby it was shown that there were 1700 fathoms of water on a spot hitherto marked on the charts as "5 fathoms doubtful." Surveys were made round the Laccadive and the Andaman Islands, at the Palk Straits, the Western Coral Banks, on the Malabar coast near Cannanore and Tellicherry, and off Parbandar. Interesting marine organisms, some of them quite new, were brought up by the trawler, especially from a depth of 250 fathoms off the Andamans. The observations for temperature have enabled the survey to construct a temperature curve which is fairly constant for all parts of those seas.

Geological Survey.—Among the investigations by the Geological Survey during the year 1888 may be mentioned the examination of the auriferous rocks known as the Dharwar rocks, bands of which occur in the gneiss mountains, from the edge of the Deccan trap in the meridian of Kaladgi, across the upper basins of the Kistna, Tangabhadra, Penner, and Cauvery Rivers. At many places in these bands of Dharwar rock, the geological officers discovered traces of extensive gold workings, the existence of which was hardly known to the present inhabitants. The investigators consider that in many places, especially in the Kolar and Maski bands, gold will be found in quantities that will repay working. The workers of past centuries used to crush the ore in saucer-like hollows in the solid, tough, trappoid rocks, with rounded granite crushers, weighing about a ton each. The supposed diamond sources in the Anantapur district of Madras were examined, but with only negative results. The coal-field of Singareni, in the Nizam's dominions, was examined; it was estimated that 17,000,000 tons of coal were available in the field. The geologists reported that the cost of raising coal into waggons at the pit's mouth ought not eventually to exceed 2 rupees a ton. Further examinations were made of the coal-bearing rocks of Western Chota Nagpore and of Rajmehal; the latter coal source cannot be thoroughly tested until bore holes are put down. The seams of coal at Kohst, in Baluchistan, were found to contain 1½ to 2 feet of good coal at times; coal from surface workings is now chiefly used in locomotives; but the best plan for permanent workings has not yet been settled. The petroleum sources at Khatun, in Baluchistan, and in the Rawal Pindi district of the Punjab, were visited by officers of the Survey; the Khatun oil is too thick to flow down a pipe for forty miles to the railway, where it has made excellent fuel. The Cashmere coal-field, in the upper valley of the Chenab, was also examined.

The report of the Cadastral Surveys and Settlements is devoid of scientific interest.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—In the course of the term which has just come to an end, Mr. J. B. Farmer, B.A., has been elected to a Fellowship at Magdalen, after an examination in botany—a subject to which no Fellowship has been allotted for many years; and the Burdett-Coutts Scholarship in Geology has been awarded to Mr. F. Pullinger, Corpus.

Mr. Hatchett Jackson will continue to act as Deputy Professor of Comparative Anatomy for the next two terms at least.

The recently founded Readership in Geography seems to have proved a success this term, as Mr. Mackinder had a class of fifty in regular attendance.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 21.—"On the Tubercles on the Roots of Leguminous Plants, with special reference to the Pea and the Bean." By H. Marshall Ward, M.A., F.R.S., F.L.S., late Fellow of Christ's College, Cambridge, Professor of Botany

in the Forestry School, Royal Indian Engineering College, Cooper's Hill.

In the Philosophical Transactions for 1887 (vol. clxxviii. B, pp. 539-562, Pls. 32 and 33) the author published the results of some investigations into the structure and nature of the tubercular swellings on the roots of *Vicia Faba* and other Leguminous plants.

The chief facts established in that paper were as follows:— That the tubercles occur in all places and at all times on the roots of Papilionaceous plants growing in the open land, but that in sterilized media and in properly conducted water-cultures they are not developed, unless the root is previously infected by contact with the contents of other tubercles. In other words, the tubercles can be produced at will by artificial infection. The author also showed that the act of infection is a perfectly definite one, and is due to the entrance into the root-hair of a hypha-like infecting tube or filament, which starts from a mere brilliant dot at the side or apex of the root-hair, passes down the cavity of the latter, traverses the cortex of the root from cell to cell, until its tip reaches the innermost cells of the cortex, where it branches and stimulates these cells to divide and form the young tubercle.

These facts of the infection were entirely new, as were the methods, and the author showed actual preparations of the infecting filaments passing down the root-hairs, at the time (June 1887).

In this paper the author described and explained the trumpet-shaped enlargements of the filaments, and the bacterium-like contents of the cells (bacteroids—gemmules), and showed that the latter arise from the former. He also pointed out that the root-hairs are distorted at the point of infection, and that the infecting filament originates there from a brilliant granule, presumably one of the bacteroids. Another important observation was that the protoplasm of the cells of the tubercle is stimulated by the activity of the bacteroids in it, and behaves like a plasmodium.

The author now draws attention to some results of his further researches into this confessedly difficult subject.

After numerous culture experiments and observations made last year (1888), it was decided to abandon the broad-bean as the subject for histological analysis, chiefly because it takes so long to exhaust its stores of reserve materials; it was better for the cultures to be made with the pea, the cotyledons of which are so much smaller, and the plant of which is more easily managed in every way in water and pot cultures, while the tubercles and their contents present no essential features of difference.

But more conclusive evidence than the above is offered for the identity of the bacteroids in the two cases. In some of the cultures made in the summer of 1888 the roots of the pea were successfully infected with bacteroids taken from the tubercles of the bean, and this is a point of importance, in view of the belief that each species of Leguminosæ may have its own species of bacteroid.

It is especially the very young root-hairs, with extremely delicate cell-walls, that are infected, and the first sign is the appearance of a very brilliant colourless spot *in* the substance of the cell-wall: sometimes it is common to two cell-walls of root-hairs in contact, and not unfrequently one finds several root-hairs all fastened together at the common point of infection. This highly refringent spot is obviously the "bright spot" referred to in the author's previous paper as the point of infection from which the infecting filament takes origin. It soon grows larger, and develops a long tubular process, which grows down inside the root-hair, and invades the cortex, passing across from cell to cell, as described in 1887.

As a matter of fact, then, the "bright spot" is the point of origin of the infecting filament; and, as a matter of inference from the experiments, it cannot but be developed from one of the "bacteroids" or "gemmules" of the tubercles. This attaches itself to the root-hair, fuses with and pierces the delicate cellulose wall, and grows out into a hypha-like filament at the expense of the cell contents. The further progress of this filament has already been described in the author's memoir in the Philosophical Transactions for 1887.

Researches were made during 1888 and 1889 with the object of learning more about the conditions which rule the development of the tubercles, and the relations of the organism to them. The experiments seem to prove conclusively that the well-being of the organism of the tubercle and that of the pea or bean go hand in hand. This of course is only so much evidence in favour of the view that we have here a case of symbiosis of the closest kind, as expressed in the previous memoir.

During the spring and summer of 1888 numerous experiments were made with water-cultures with beans, allowed to germinate in soil so as to be infected by the "germs" therein, as demonstrated previously. Several dozens of such cultures were made, and some of them placed in the dark, others in the ordinary light of the laboratory, and some in a well-lighted greenhouse. Tables were prepared showing the number of leaves, living and dead, the condition of the roots, the height of the stem, and so forth, as recorded every week or so (or at shorter intervals) when the plants were examined. It resulted that, when the beans are in any way so interfered with that they do not assimilate more material than is necessary for the growth and immediate requirements of the plant, the infecting organism either gains no hold at all on the roots, or it forms only small tubercles which are found to be very poor in "bacteroids": in some cases the starving plants began to develop tubercles, which never became larger, and in which the infecting organism seemed to be in abeyance. Whether this is due to the bacteroids being developed in small quantities, or to their absorption into the plant, is still a question.

In these tubercles the chief difference was the paucity in bacteroids, and the prominence of the branched filaments in the cells.

In the spring of this year (1889) the author started a series of water-cultures of beans, infected artificially by placing the contents of tubercles on their root-hairs, and kept the roots oxygenated by passing a stream of air through the culture liquid for twenty-four hours at intervals of a few days: here again the increased growth of the plants—not compensated by increased assimilation—seemed to cause the suppression of the tubercles, or the formation of very poor ones only. These and similar experiments lead to the conclusion that the organism which induces the development of the tubercles is so closely adapted to its conditions that comparatively slight disturbances of the conditions of symbiosis affect its well-being: it is so dependent on the roots of the Leguminosæ, that anything which affects their well-being affects it also.

Some experiments with peas, which are now being tabulated, may throw some light on the wider question which has been raised of late, as to the alleged connection between the development of these tubercles and the increase of nitrogen in Leguminous plants. Thirty-two peas were sown in separate pots of silver-sand, or soil, in five batches of six each, and one of two, and treated in various ways.

The tubercles were developed on all but one of the plants, except those in the completely sterilized media. The evidence at present goes to show that *the Leguminous plant gains nitrogen by absorbing the nitrogenous substance of the bacteroids from the tubercles*; that nitrogenous substances are thus brought by the "bacteroids" ("gemmules") of the infecting organism of the plant; and that, finally, no satisfactory explanation seems forthcoming as to how the organism obtains this nitrogen in certain cases where no compounds of nitrogen have been added. At any rate, if we regard the pot of sand and its pea as one system, there is in some cases *a distinct gain of nitrogen in the crop, and in the sand at its roots.*

The author then refers to the literature since 1887, and reviews two papers by Praźmowski which bear directly on these researches.

"To sum up, Praźmowski's account of the whole matter confirms that given to the Royal Society by the author in 1887, excepting that he interprets the origin and nature of the bacteroids differently; he regards them as produced from the *contents* of the filaments—as germ-like bodies developed in the interior of the filaments, and not budded off from them. This is hypothesis only, however, for the author expressly states (p. 253), 'Direct habe ich ihre Theilungen nicht gesehen, obgleich ich mir die Mühe gab, sie in den verschiedensten Nährmedien und unter den verschiedensten äusseren Bedingungen zu züchten.' He concludes they can only multiply in the still *living* protoplasm.

"As to the shapes of the bacteroids and tubercles, Praźmowski's statements agree with those of previous observers, and he also remarks the plasmodium-like appearance of the cell protoplasm at certain stages, as noticed by myself. Some observations on a possible spore-formation need not be dwelt upon, as he recognized his mistake in a subsequent paper in 1889.

"He leaves the question as to the origin of the bacteroids by budding or otherwise quite undecided, having failed to satisfy himself whether my suggestion is right or not; at the same time, he fully agrees with me and others in believing that these tiny bodies must be the infecting agents, easily and abundantly distributed as they are in the soil, water, &c."

The author concludes by saying:—

"I think it will be admitted by all who study the literature of this subject, that the only real point at issue between Prażmowski and myself is the nature of the bacteroids and their origin from the filaments. I interpreted them as extremely minute budding 'gemmules,' and not bacteria; Prażmowski, with Beyerinck, regards them as true Schizomycetes. We have all alike failed to actually see the process of budding or fission, a fact which will surprise no one who has examined these extremely minute bodies, which are, as Beyerinck rightly puts it, among the smallest of living beings.

"The fact of infection, and the mode of infection, by means of a hypha-like filament passing down the root-hair were definitely established by myself in 1887, and it is satisfactory to find it confirmed in every essential detail by Prazmowski. Our views as to the symbiosis, the struggle between the protoplasm and the 'gemmules' (or 'bacteroids') are the same; though Prażmowski and Beyerinck carry the matter a step further in definitely inferring the absorption of the conquered bodies of the latter, a point in part supported by some of my experiments.

"As to the occurence, origin, and structure of the tubercles, Prażmowski's account is simply in accordance with my own; and it is interesting to note how many points of detail—the distortions of the root-hairs, the relations of the branching filaments to the nuclei and cell-contents, and those of the incipient tubercle to the end of the filament, for example—are confirmed by him."

Chemical Society, November 7.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—Isolation of a tetrahydrate of sulphuric acid existing in solution, by Mr. S. U. Pickering. The freezing-points of mixtures of sulphuric acid and water form three distinct curves representing the crystallization of water, of the hydrate, $H_2SO_4 + H_2O$, and of sulphuric acid, and the highest point of each of these curves is in exact correspondence with the composition of the substance which crystallizes out. Solutions containing between 40 and 75 per cent. of sulphuric acid had not hitherto been frozen; but it appeared to the author that if his former deductions from the irregularities in the curves representing the densities and other properties of the solutions of the acid were correct, an independent curve representing the crystallization of a new hydrate should occupy this interval, and that this new hydrate should have the composition $H_2SO_4 + 5\frac{1}{2}H_2O$, or $H_2SO_4 + 4H_2O$. Experiment has proved it to be the latter. The two branches of the new curve rise from about $-80°$, and meet in a sharply marked angle at a point corresponding with the composition of the tetrahydrate, the temperature at which this point is reached being $-25°$. The tetrahydrate forms large, well-defined, hard crystals. The author regards the isolation of this hydrate as affording fresh confirmatory evidence of the hydrate theory of solution.—Additional observations on the magnetic rotation of nitric acid, and of hydrogen and ammonium chlorides, bromides, and iodides in solution, by Dr. W. H. Perkin, F.R.S. In his previous experiments, the author has limited his observations on nitric acid to the pure acid HNO_3; he has now examined a somewhat diluted acid, and the results indicate that HNO_3 unites with water, forming an acid analogous to orthophosphoric acid, viz. $(OH)_3NO$. The experiments on hydrogen chloride, bromide, and iodide were originally made on single samples in a very concentrated solution of each. These gave abnormally high results—rather more than twice the values calculated for the pure compounds—but on examination of solutions of different strengths, it was found that the rotation increases up to a dilution equivalent to about six or seven molecular proportions of water, to one molecular proportion of hydride, the value then remaining practically stationary. To see whether the solvent had any influence, a solution of hydrogen chloride in isoamyl oxide was examined, and was found to give values nearly identical with those calculated from the chlorine derivatives of the paraffins; and there can be little doubt that, if the other hydrides could be examined in a similar way, analogous results would be obtained. As union with water should reduce the rotations, the results are at present inexplicable. The compounds with ammonia and the compound ammonias have also been further examined; the results are remarkable when considered in relation to those afforded by the hydrides, as the rotations found, instead of being those calculated from the results obtained in the case of the paraffin derivatives, or those found in the case of hydrogen chloride dissolved in isoamyl oxide, nearly correspond with those required on the assumption that the hydrides are present in aqueous solution together with ammonia. The rotations, however, do not vary with the strength of the saline solutions. The author's explanation of this is that when the salts are dissolved in water, they dissociate almost entirely into the hydride and the amine, the hydride undergoing an increased rotation on account of its being in aqueous solution. In the case of triethylamine hydrochloride the numbers are lower, and there is evidently less dissociation; and in the case of tetrethylammonium chloride little or no dissociation appears to take place. Solutions of ammonium iodide and diethylamine hydrochloride in absolute alcohol gave somewhat lower numbers than aqueous solutions, indicating somewhat smaller, although still large, amount of dissociation. Ammonium nitrate and acid ammonium sulphate in aqueous solution give numbers agreeing closely with the calculated values, and apparently do not dissociate to any appreciable extent. In the discussion which followed the reading of this paper, Dr. Gladstone, F.R.S., stated that, on examining Dr. Perkin's solution of hydrogen chloride in isoamyl oxide, he found that the refraction and dispersion values deduced for the chloride are very much smaller than those afforded by aqueous solutions.—Phosphoryl trifluoride, by Prof. T. E. Thorpe, F.R.S., and Mr. F. J. Hambly. Phosphorus oxyfluoride, POF_3, may be easily and conveniently made by heating a mixture of cryolite and phosphoric oxide, and collecting the products at the mercurial trough.—Acetylation of cellulose, by Messrs. C. F. Cross and E. J. Bevan. On heating cotton cellulose with acetic anhydride and zinc chloride, a product is obtained which appears to be a pentacetyl derivative of cellulose. The compound is very stable, and on alkaline hydrolysis yields a substance having the properties of a normal cellulose. It would therefore appear that all the oxygen of the cellulose molecule acts as hydroxylic oxygen, and, in view of this result, a reconsideration of the present ideas as to the constitution of cellulose is rendered necessary.—Action of light on moist oxygen, by Dr. A. Richardson. The presence of liquid water very much facilitates the oxidation of many substances under the combined influence of sunlight and oxygen, but if the water is present as aqueous vapour, the decomposition is exceedingly slow, and in some cases is entirely arrested. The author finds that peroxide of hydrogen is formed when water containing pure ether, or pure water acidified with pure sulphuric acid, is exposed to light in an atmosphere of oxygen, and draws the conclusion that the oxidation of substances under the influence of light involves in many cases initially an oxidation of water to hydrogen peroxide, and that the oxidation of the compound is the result of a secondary interaction between it and the hydrogen peroxide. In the discussion which followed the reading of the paper, Prof. Armstrong pointed out that, whilst Dr. Richardson assumed that water was directly oxidized when mixed with ether and exposed to oxidation, Mr. Kingzett had argued—and in the case of turpentine had adduced weighty experimental evidence—that the hydrogen peroxide was a secondary product formed by the action of water on an organic peroxide. The use of ether or sulphuric acid, which Dr. Richardson had added with the object of protecting the peroxide, was to be deprecated, since hydrogen peroxide in weak solutions was comparatively stable; no satisfactory evidence had been adduced that the peroxide is formed in the absence of a third substance when water and oxygen are exposed to light. Prof. Dunstan remarked that he had found that hydrogen peroxide was not formed when pure ether was used, although a substance was obtained which was capable of liberating iodine from potassium iodide. The President said that in experiments which he and Captain Abney had made together on the fading of water-colours, the action of aqueous vapour had been most strikingly apparent; colours were found to be stable on exposure to light in dry air, which were considerably affected when aqueous vapour was present.—α-β-dibenzoylstyrolene and the constitution of Zinin's lepiden derivatives, by Prof. F. R. Japp, F.R.S., and Dr. F. Klingemann. The authors have continued their investigation of the interactions of dibenzoylstyrolene (anhydracetophenonebenzil), and find that there is an almost perfect parallelism in behaviour between it and one of the three isomeric oxy epidens prepared by Zinin, viz. the "acicular oxylepiden" melting at 220°. The various compounds obtained by them stand to the corre-

sponding compounds of the lepiden series in the relation of triphenyl derivatives of furfuran to tetraphenyl derivatives, a relation which is exhibited in the first place by dibenzoylstyrolene and oxylepiden themselves. Like "acicular oxylepiden," dibenzoylstyrolene yields two isomeric derivatives on heating; the isomeride formed in larger quantity in each case is almost certainly a derivative of crotolactone, whilst the isomeride formed in smaller quantity is probably a stereometric isomeride of "acicular lepiden" and dibenzoylstyrolene respectively.—Ethylic $\alpha\alpha_1$-diacetyladipate, by Prof. W. H. Perkin.—(1 : 2) methylethylpentamethylene, by Dr. T. R. Marshall and Prof. W. H. Perkin.—Action of reducing agents on α-ω-diacetylpentane; formation of (1 : 2) methylethylhexamethylene, by Dr. F. S. Kipping and Prof. W. H. Perkin.—Action of reducing agents on α-ω-diacetylpentane; formation of (1 : 2) dimethylheptamethylene, by the same.—Oxyamidosulphonates and their conversion into hyponitrites, by Dr. E. Divers, F.R.S., and Mr. T. Haga. The oxyamidosulphonates are the sulphazidates of Fremy, which Claus and Raschig have shown to be monosulphonic derivatives of hydroxylamine. The authors find that these compounds on treatment with alkali, instead of yielding hydroxylamine and the alkaline sulphate as asserted by Claus and Raschig, and as it is admitted they do when hydrolyzed by an acid, are converted exclusively into sulphite and hyponitrite, thus, $2HO . NH . SO_3K + 4KHO = (KON)_2 + 2K_2SO_3 + 4H_2O$. The reducing action of the oxyamidosulphonates has been examined, and it is found that the generally accepted view that it is due to the supposed conversion of these salts into sulphate and hydroxylamine, the latter then acting upon the copper hydroxide in the usual way, is untenable.—The alloys of lead, tin, zinc, and cadmium, by Mr. A. P. Laurie. In extension of his previous observations (Trans. Chem. Soc., 1888, 88), the author has made voltaic cells with the various alloys, and has thus compared their behaviour with that of the single metal by means of an electrometer. He concludes that the metals now examined do not combine together, thus confirming Matthiessen's conclusions.

November 21.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—The law of the freezing-points of solutions, by Mr. S. U. Pickering. —The constituents of flax, by Messrs. C. F. Cross and E. J. Bevan. As a result of their examination of the cuticular constituents of the fibre, the authors have isolated ceryl alcohol, two fatty acids, of which one appears to be cerotic acid, an oily ketone, and a residue of complex, ill-defined, inert compounds yielding "ketones" on hydrolysis. These "ketones" have the characteristic odour of raw flax and flax goods, and from their property of emulsifying with water undoubtedly exercise an important influence on the wet processes of fine spinning of flax. The pectic group of constituents associated with the cellulose in the fibre proper is found to yield mucic acid on oxidation with dilute nitric acid, and flax cellulose when oxidized with potassium permanganate yields, in addition to oxycellulose and oxalic acid, acid substances from which furfural is obtained on acid hydrolysis.—Acetylcarbinol (acetol), by Prof. W. H. Perkin and Dr. J. B. Tingle. The authors announce the preparation of anhydrous acetylcarbinol.

Zoological Society, November 19.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of October 1889, and called special attention to the arrival of a young male Gaur (*Bibos gaurus*) from Pahang, one of the native States in the Malay Peninsula, presented to the Society by Sir Cecil C. Smith, the Governor of the Straits Settlement.—The President exhibited and made remarks on a head of an African Rhinceros (*Rhinoceros bicornis*) with a third posterior horn partially developed. The animal from which it was taken had been shot by Sir John Willoughbey, in Eastern Africa.—The Secretary exhibited a skin of an albino variety of the Cape Mole-Rat (*Georychus capensis*), forwarded to the Society by the Rev. G. H. R. Fisk, of Cape Town.—Mr. A. Smith-Woodward exhibited and made remarks on a portion of the rostrum of an extinct Saw-fish (*Sclerorhynchus*) from the chalk of Mount Lebanon.—Mr. Goodwin exhibited and made remarks on specimens of some rare Paradise Birds obtained by him on Mount Owen Stanley, New Guinea, when in company with Sir William Macgregor's recent expedition; also some photographs taken on the same occasion.—A communication was read from the Rev. Thomas R. R. Stebbing and Mr. David Robertson containing the descriptions of four new British Amphipodous Crustaceans. These were named *Sophrosyne robertsoni*, *Syrrhoe fimbriata*, *Podoceropsis palmatus*, and *Podocerus cumbrensis*. Of these, *Sophrosyne robertsoni* belonged to a genus first observed at Kerguelen Island.—Mr. G. W. Butler read a paper on the subdivison of the body-cavity in Lizards, Crocodiles, and Birds, in which an attempt was made to analyze the complex conditions of the membranes observable in the last two groups, and to express them in terms of the simpler structures found in the Lizards.—Mr. J. H. Leech read the third part of his paper on the Lepidoptera of Japan and Corea, comprising an account of the *Noctuæ* and *Deltoidæ*; in all upwards of 475 species. Of these forty-six were now described as new to science, and two others were considered to be varietal forms. —Mr. R. Lydekker read a paper on the remains of a Theriodont Reptile from the Karoo System of the Orange Free State. The remains described were an associated series of vertebræ and limb-bones of a comparatively large Theriodont, which was probably different from any described form. The humerus was of the normal Theriodont type, and quite distinct from the one on which the genus *Propappus* had been fonnded, which the author considered to belong to a form closely allied to, if not generically identical with, *Pariasaurus*.—Mr. G. B. Sowerby read the descriptions of thirteen new or rare species of Land-Shells from various localities.—A communication was read from Mr. Edward A. Minchin containing an account of the mode of attachment of the embryos to the oral arms of *Aurelia aurita*. It was shown that the embryos of *Aurelia aurita* are developed on the arms, in broad capsules formed as evaginations of the walls of the oral groove, and that the capsules increase in size with the addition of more embryos.

Linnean Society, November 21.—Mr. W. Carruthers, F.R.S., President, in the chair.—Prof. Duncan exhibited and made remarks on a stem of *Hyalonema Sieboldii*, dredged between Aden and Bombay, a remarkable position, inasmuch as this Glass Sponge had not previously been met with in any waters west of the Indian Peninsula. Prof. Stewart criticized the occurrence, and referred to a parasite on the Sponge which had been found to be identical with one from the Japanese seas. —Mr. James Groves exhibited and gave some account of a new British Chara, *Nitella batrachiosperma*, which had been collected in the Island of Harris.—Mr. Thomas Christy exhibited some bark of *Quillaia saponaria* from Chili, which has the property of producing a great lather, and is extensively used for washing silk and wool. It is now found to solidify hydrocarbon oils and benzoline, and thereby to insure their safe transport on long voyages; a small infusion of citric acid rendering them again liquid.—Dr. F. Walker exhibited and made remarks on some plants collected by him in Ireland.—Mr. W. Hachett Jackson gave an abstract of an elaborate paper on the external anatomical characters distinctive of sex in the chrysalis, and on the development of the azygos evident in *Vanessa Io*.—Mr. E. B. Poulton followed by giving a *résumé* of his researches on the external morphology of the Lepidopterous pupa.—Mr. J. H. Leech gave an account of some new Lepidoptera from Central China.

PARIS.

Academy of Sciences, December 2.—M. Hermite in the chair.—On the fermentation of stable manure, by M. Th. Schlœsing. A series of experiments has been carried out by the author for the purpose of ascertaining whether, during fermentation under cover from the air, the manure of farmyards liberates nitrogen, as it is known to liberate a mixture of carbonic acid and methane. He finds that at the temperature of 52° C. no gaseous nitrogen is generated from the decomposition of nitric compounds; nor is any nitric combination formed by oxidation of ammonia in presence of organic substances. The organic matter loses more carbon than oxygen, the proportion of hydrogen remaining about the same. The reading of the paper was followed by some remarks by M. Berthelot on the same subject.—Remarks on the diastases secreted by *Bacillus heminecrobiophilus*, by M. Arloing. These researches show that under artificial cultivation this organism secretes several soluble ferments, enabling it to prepare for assimilation all the organic substances needed for the nutrition and development of a living being; and that amongst these ferments, or associated with them, there is one that transforms the organic matter, while liberating gases—that is, exercises a function hitherto attributed to the micro-organisms themselves, and not to their secretions.—Verbal report on the work of E. D. Suess, entitled "Das Antlitz der Erde," vols. i. and ii., 1885 and 1888, by M. Daubrée. This fundamental treatise on the constitution of the earth is here

described as a summary of the facts already established regarding the geology of the various parts of the globe, the essential features of its present mountain ranges and depressions, and the successive movements of the terrestrial crust of which these are the outcome. The work marks a new departure in the progress of physical geography.—Observations of Swift's new comet made with the Brunner equatorial at the Observatory of Toulouse, by M. B. Baillaud; and with the large equatorial at the Observatory of Bordeaux, by MM. G. Rayet and Picart. All these observations, extending from November 21 to November 27, give the same results: comet very faint and greatly diffused, making observations very difficult. Tables are also given of observations made at Algiers by MM. Trépied, Rambaud, Sy, and Renaux, during the same period.—Mechanical realization of thermodynamic phenomena, by M. Chaperon. Purely mechanical systems may be conceived, which present a striking analogy to heat-engines in respect of their influence on finite movements. The author here describes one of these systems, which is distinguished by its extreme simplicity.—On the correspondence between the characteristic equations of gases, by M. Ladislas Natanson. The author here shows that Wroblewski's posthumous memoir, published by the. Vienna Academy in November 1888, forms a natural complement to Van der Waal's law that at absolute, that is, *corresponding* temperatures proportional to the critical temperatures of the different bodies, the pressures, P, of their saturated vapours are proportional to the respective critical pressures.—Method of measuring the spheric and chromatic aberrations of the objectives of the microscope, by M. C. J. A. Leroy. Findine in an artificial eye certain effects connected with the aberrations of sphericity and refrangibility, the author has applied the method known as "Cuignet's keratoscopy" to the study of the aberrations of the eye, and of the objectives of the microscope. His present observations are confined to the objectives alone.—On the electric conductivity of the Eiffel Tower and its conductors, by M. A. Terquem. It is shown that the tower with its complete system of lightning conductors, constructed under the direction of MM. Becquerel, Berger and Mascart, is calculated to afford perfect security for a considerable space round about.—Fresh researches on the preparation and density of fluorine, by M. Henri Moissan.—Papers were submitted by M. Daniel Berthelot, on the electric conductivities and multiple affinities of aspartic acid; by MM. E. Jungfleisch and L. Grimbert, on some facts relative to the analysis of sugars; by M. G Colin, on the varying effects of virulent substances used for inoculating animals; by M. P. Fliche, on the silicified woods of Algeria; by M. Stanislas Meunier, on the Phu-Hong meteorite, with remarks on the limerick type; and by M. Léon Teisserenc de Bort, on the distribution of atmospheric pressure over the surface of the globe.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, DECEMBER 12.

ROYAL SOCIETY, at 4.30.—The Relation of Physiological Action to Atomic Weight: Miss H. J. Johnstone and Prof. T. Carnelley.—An Experimental Investigation into the Arrangement of the Excitable Fibres of the Internal Capsule of the Bonnet Monkey (Macacus sinicus): Dr. Beevor and Prof. V. Horsley, F.R.S.—On the Effect of the Spectrum on the Haloid Salts of Silver: Capt. Abney, F.R.S., and G. S. Edwards.—Magnetic Properties of Alloys of Nickel and Iron: Dr. Hopkinson, F.R.S.

MATHEMATICAL SOCIETY, at 8.—On the Radial Vibrations of a Cylindrical Shell: A. B. Basset, F.R.S.—Note on 51840-Group: G. G. Morrice.—On the Flexure of an Elastic Plate: Prof. H. Lamb, F.R.S.—Notes on a Plane Cubic and a Conic: R. A. Roberts.—Complex Multiplication Moduli of Elliptic Functions for the Determinants − 53 and − 61: Prof. G. B. Mathews.

THE EPIDEMIC OF INFLUENZA.

FOR the first time after an immunity of nearly half a century, our country is again threatened with an epidemic of influenza. The accounts we receive of epidemic illness in Russia, in Germany, and last of all in Paris, seem to make its irruption here every week more imminent. The question will, however, naturally be asked by the public, whether there is any real ground, in the history and in what is known of the nature of the disease, for such an apprehension? Is it a disease really brought from a distance? Is it anything more than the general prevalence of catarrhal affections, of colds and coughs, which the time of year, and the remarkably unsettled weather we have lately experienced, make readily explicable without any foreign importation? Indeed, is influenza, after all, anything more than a severe form of the fashionable complaint of the season?

To answer the last question first, and so to put it by, there can be little doubt that influenza is a distinct, specific affection, and not a mere modification of the common cold. The grounds for this belief cannot be fully stated here, but may be gathered by reference to the descriptions of the disease as seen in former outbreaks by physicians of the older generation; for instance, by Sir Thomas Watson in his classical "Principles of Physic," or the late Dr. Peacock in his article in Quain's "Dictionary of Medicine."

These symptoms, the history of the disease, and its distribution, all justify us in treating it as a distinct and specific disease, which when it is prevalent will rarely be mistaken, though, with regard to isolated and sporadic cases, difficulties of diagnosis may arise. About its nature, or its affinities with other diseases, it is unnecessary to speculate. It will be sufficient to inquire what its recorded history in the past justifies us in expecting as to its behaviour in the future. There are few cases in which history proves so important an element in the scientific conception of a disease as it does in that of influenza. For hardly any disease shows a more marked tendency to occur in epidemics—that is, in outbreaks strictly limited in point of time. After long intervals of inaction or apparent death, it springs up again. Its chronology is very remarkable. Though probably occurring in Europe from very early times, it first emerged as a definitely known historical epidemic in the year 1510. Since then, more than 100 general European epidemics have been recorded, besides nearly as many more limited to certain localities. Many of them have in their origin and progress exhibited the type to which that of the present year seems to conform. We need not go further back than the great epidemic of 1782, first traceable in Russia, though there believed to have been derived from Asia. In St. Petersburg, on January 2, coincidently with a remarkable rise of temperature from 35° F. below freezing to 5° above, 40,000 persons are said to have been simultaneously taken ill. Thence the disease spread over the Continent, where one-half of the inhabitants were supposed to have been affected, and reached England in May. It was a remarkable feature in this epidemic that two fleets which left Portsmouth about the same time were attacked by influenza at sea about the same day, though they had no communication with each other or with the shore.

There were many epidemics in the first half of this century; and the most important of them showed a similar course and geographical distribution. In 1830 started a formidable epidemic, the origin of which is referred to China, but which at all events by the end of the year had invaded Russia, and broke out in Petersburg in January 1831. Germany and France were overrun in the spring, and by June it had reached England. Again, two years later, in January 1833, there was an outbreak in Russia, which spread to Germany and France successively, and on April 3, the first cases of influenza were seen in our metropolis; "all London," in Watson's words, "being smitten with it on that and the following day." On this same fateful day Watson records that a ship approaching the Devonshire coast was suddenly smitten with influenza, and within half an hour forty men were ill. In 1836 another epidemic appeared in Russia; and in January 1837, Berlin and London were almost simultaneously attacked. Ten years later, in 1847, the last great epidemic raged in our own country, and was very severe in November, having been observed in Petersburg in March, and having prevailed very generally all over Europe.

Some of these epidemics are believed to have travelled still further westward, to America; but the evidence on this point seems less conclusive. Without entering on further historical details, and without speculating on the nature of the disease, we may conclude that these broad facts are enough to show that a more or less rapid extension from east to west has been the rule in most of the great European epidemics of influenza; and that therefore its successive appearance in Russia, Germany, and France, makes its extension to our own country in the highest degree probable.

There are, it is true, certain facts on the other side, but they appear much less cogent. Since our last great visitation, certain epidemics of influenza have been recorded on the Continent which have not reached our shores. One was that of Paris in 1866–67; another at Berlin in 1874–75, of a disease described by the German doctors as influenza, and of great severity, affecting all classes of society. But in all epidemic and even contagious diseases there are outbreaks which seem to be self-limited from the first, showing no tendency to spread. This has been notably the case with plague and cholera. On the other hand, when an epidemic shows an expansive and progressive character, it is impossible to predict the extent to which it may spread. And the present epidemic, it must be confessed, appears to have this expansive character.

Many interesting points are suggested by this historical retrospect. What is the meaning of the westward spread of influenza, of cholera, and other diseases? Is it a universal law? To this it must be said, that it is by no means the universal law even with influenza, which has spread through other parts of the world in every kind of direction, but it does seem to hold good for Europe, at least in the northern parts. The significance of this law,

as of the intermittent appearances of influenza, probably is that this is in Europe not an indigenous disease, but one imported from Asia. Possibly we may some day track it to its original home in the East, as the old plague and the modern cholera have been traced.

As regards, however, the European distribution of influenza, it has often been thought to depend upon the prevalence of easterly and north-easterly winds. There are many reasons for thinking that the contagium of this disease is borne through the air by winds rather than by human intercourse. One reason for thinking so is that it does not appear to travel along the lines of human communications, and, as is seen in the infection of ships at sea, is capable of making considerable leaps. The mode of transmission, too, would explain the remarkable facts noticed above of the sudden outbreak of the disease in certain places, and its attacking so many people simultaneously, which could hardly be the case if the infection had to be transmitted from one person to another.

Another important question, and one certain to be often asked, is suggested by the last—namely, whether influenza is contagious. During former epidemics great care was taken to collect the experience of the profession on this point, and its difficulty is shown by the fact that opinions were much divided. Some thought the disease could be transmitted by direct contagion, while others doubted it. But there was and is a general agreement that this is not the chief way in which the disease spreads, either in a single town, or from place to place.

We must avoid the fascinating topic of the cause of influenza, or our limits would be speedily outrun. But one simple lesson may be drawn from the facts already mentioned—namely, that the disease is not produced by any kind of weather, though that, of all possible causes of disease, is the one most often incriminated in this country. It is true that some of our worst epidemics have occurred in winter, but several have happened in summer; and the disease has been known in all parts of the world, in every variety of climate and atmospheric condition; so that it is certainly not due to a little more or less of heat or cold, moisture or dryness. Its constancy of type, the mode of its transmission, its independence of climatic and seasonal conditions, all suggest that its cause is "specific,"—that is, having the properties of growth and multiplication which belong to a living thing.

Whether the disease affects the lower animals is not absolutely certain, but the human epidemic has often been preceded or accompanied by an epidemic among horses of a very similar disease. It is pretty well known that such a disease is now very prevalent among horses in London. Nearly three weeks ago, one of the railway companies in London had 120 horses on the sick list, and the epidemic is still by no means extinguished. To a certain extent this must be taken as prognostic of human influenza.

It may be asked, if the influenza is really to come, can we form any notion how soon it is likely to appear? On such a point little beyond speculation is possible, for the rate at which the disease travels is extremely variable. Generally, it has taken some weeks, or even months, to traverse Europe, but occasionally much less, as, for instance, in 1833, when it appeared to travel from Berlin to Paris in two days. It is now barely a month since the epidemic became noticeable in Petersburg, where, according to a correspondent of the *British Medical Journal*, it began on November 15 or 17, though sporadic cases had undoubtedly occurred earlier. In the beginning of December it was already widely spread throughout Russsia, and, as it would seem from the published accounts, must have been in Berlin about the same time. In Paris the first admitted and recorded cases occurred about December 10, though doubtless there were cases before that date. Both public and private accounts report it exceedingly prevalent there now. In London, notwithstanding the abundance of colds and coughs, and the mysterious rumours which have been afloat, it appears to the present writer doubtful whether any cases of true influenza have yet occurred. But according to its apparent rate of progress, it might, if coming from Paris, have already arrived here; and it may be breaking out even while these lines are going through the press. But, on the whole, one would be disposed to give the epidemic another week or two. If its distribution depends, as it seems to do, on the winds, it is impossible to prophesy with much plausibility. A steady breeze setting in from one of the affected places might bring us an invasion in a very short time; but the current of air would have to be continuous over the whole district. Light local winds, whatever their direction, would, if the hypothesis be correct, have little effect. On the other hand, a steady frost, with an "anticyclone" period, might effectually keep off the disease. If, then, there is anything in the views above stated, prophecy belongs rather to the province of the weather-doctors than of the medical doctors.

Should the prospect seem a grave one, it may be some consolation to remember that an epidemic of influenza rarely lasts more than a few weeks—three to six—in one place; that it is rarely a fatal disease, though affecting large numbers of people; and that the present epidemic seems to have displayed on the Continent a decidedly mild type, which, according to the general rule, it is likely to retain.

J. F. P.

THE HORNY SPONGES.

A Monograph of the Horny Sponges. By Robert von Lendenfeld. (London: Published for the Royal Society by Trübner and Co., Ludgate Hill, 1889.)

WITHIN the last few years, and as a direct result of the famous Expedition of the *Challenger*, three most important monographs of the sponges belonging to the groups of the Hexactinellida, Monaxonida, and the Tetractinellida have been published, nor must the valuable contributions by Poléjaeff to the history of the remaining groups, Calcarea and Keratosa, be overlooked. The Calcarea had the advantage of having been already monographed by Haeckel, and so there only remained the Horny Sponges to be fully described, in order that the natural history of the sponges should be up to date.

Such a work has now been accomplished—thanks to the liberality of the Royal Society—by the labour and scientific skill of Dr. Robert von Lendenfeld. This monograph forms a fine quarto volume of over 900 pages, with an atlas of fifty lithographed plates.

While a student at the University of Graz, Lendenfeld

tells us, his time was chiefly spent in the zoological laboratory of Prof. F. E. Schulze, then engaged on those researches on the natural history of sponges with which his name will ever be associated. This led him to take a special intest in the group, and to work out its history, first in the Mediterranean, and then at Melbourne and other places on the southern coast of Australia—a coast exceedingly rich in organisms of this class. From Melbourne, New Zealand was visited, and the Christchurch and Dunedin collections were examined. Next, that apparent El Dorado of the spongologist, Sydney, was explored, and, thanks to the splendid liberality of Sir William Macleay, Lendenfeld was enabled to establish a laboratory at the water-edge, and to study in a very thorough manner the sponges of this district.

With such abundant material, and with such ready help, nothing was wanting to work out the structural history of the species of the group. But to describe and name them, reference to type specimens was, above all things, necessary, and these latter were to be found most conveniently in the British Museum; thither, therefore, Lendenfeld came, early in 1886, at first resolved to write an account of the Australian Horny Sponges; but fortunately finding, during the progress of this work, that so great a proportion of the known forms were Australian, he determined to make a complete monograph of the group, and hence the volume which we proceed to notice.

This monograph of the Horny Sponges is divided into three parts: (1) an introduction, containing a brief historical summary and a detailed list of publications relating to sponges; (2) an analytical portion, devoted to the systematic description of all the known Horny Sponges; and (3) a synthetical part, in which the anatomy and physiology of sponges, especially of Horny Sponges, are treated, and their phylogeny, systematic position, and classification discussed.

Of the very extensive and scattered literature relating to the sponges, a most excellent bibliography is given; the papers are arranged alphabetically under their authors' names, but the publications of each author are given chronologically; the number of pages in each memoir is given, but, unfortunately, no reference is made to illustrations; abstracts and translations of papers are always quoted.

Considering the genus as "the important unit," the analytical part consists essentially of a series of monographs of the genera of Horny Sponges, but "species" as such are described; and the author has "done his best to make the different species equivalent," though this has been difficult of achievement. In those cases where he has felt compelled to establish varieties, he has followed the plan of E. Haeckel and F. E. Schulze, and has divided the whole species into "the requisite number of equivalent varieties." The total number of the species and varieties described amounts to 348, of which no less than 258 have been found in the Australian area.

It would not be possible, within any reasonable space, to give any satisfactory details of the analytical portion of this monograph. The descriptions of each genus are grouped into—an historical introduction; a sketch of the shape, size, colour, surface, and rigidity characteristic of the group; an account of the canal system, skeleton, with notes on the histology and physiology; the affinities of the genus; statistics of the species, with a key thereto, and details of distribution. Doubts must of necessity arise as to the exact limits that each author would ascribe to the species described by him, and in doubtful cases of this sort Dr. Lendenfeld has adopted the plan of placing no authors' names after them, but gives a full list of synonyms; we think it a pity that in these lists the memoirs, instead of being quoted, are simply referred to by numbers, for the explanation of which one must refer to the bibliographical list.

It is in the synthetical part, in which the general results are discussed, that the chief interest of this work lies, at least for the general reader. Here we have the questions of the general structure and evolution of sponges as a group considered, and their classification and systematic position discussed; and finally, as the fashion of some authors is, "an ancestral tree of the families" is given. Starting with the story of the metamorphic development of sponges, we find the primitive sponge defined as consisting of a simple ento- and ectoderm, and a thin mesoglœa—a very primitive mesoderm—between the two. Dr. Lendenfeld thinks that it is now generally acknowledged that the Physemaria, which Haeckel considered as "Gastreaden der Gegenwart," are not sponges at all, but Protozoa, so that they need not here be taken into account. Of course, it is evident that the views about these Physemarias, held at present by Haeckel, were, at the time of his thus writing, unknown to Dr. Lendenfeld. The modified Gastræa is traced onwards in its development, and the morphology of the adult structures are passed under review; their want of symmetry—and the exceptions are but few—is noted. None of the Horny Sponges are green; blue is never observed in the group, the range of colour being from light yellow to dark brown, light to dark red, and light to a dark, almost black, violet; the colour is lost in all, with a few exceptions, such as in *Aplysilla violacea*, when the sponge is preserved. The Horny Sponges would seem never to imitate their surroundings in colour, but it is suggested that in some cases the intense vivid colours may have the effect of frightening their enemies.

An attempt is made to account for the shape of the sponge conuli as the result of two pressure forces and to express this by formula. The biological student will scarcely be grateful for this, and is likely to be bewildered when he reads that "the conuli are hyperbolic rotatory bodies, formed by the rotating of the hyperbola,

$$y = (p \, . \, x)/(t + t \, . \, x),$$

round an axis parallel to the direction of pressure through the summit of the conulus." The canal system is described in some detail, the author not confining himself to the Horny Sponges. In contrasting this system in the Hexactinellida and the Hexaceratina, there seems some little confusion as to the comparative "tenderness" of the structures. The absence of spicules (siliceous) in the fibres is considered as the characteristic feature of the Horny Sponges, which distinguishes them from their siliceous ancestors; but in the superficial fibres of Aulena, echinating proper spicules occur; in the ground substance of several genera of Spongeliadæ, microsclera are

to be found, while in Darwinella, triaxon horny spicules abound.

Very interesting accounts are given of the connective tissue, muscle cells, and nervous system. Stewart's account of the "palpocils" is accepted; and, although Prof. Stewart's specimens are the only ones which show these organs properly, yet Lendenfeld thinks that, when groups of converging sense-cells are observed (in sections) below the continuous surface, these may be regarded as the cells of a "retracted" palpocil.

The researches of the author have thrown but little fresh light on the subject of the occurrence of the strange "filaments" in the species of the genus Hircinia; these filaments are generally more abundant in the superficial layer than in the interior of the sponge. They may be isolated, or arranged in bundles of varying thickness, in which they are parallel. Such bundles are particularly conspicuous in *H. gigantea*, where they form a pretty uniform network which pervades the whole of the sponge. The filaments are never straight: they may be continuously and simply curved, or they are undulating. The latter form of curvature is particularly frequently observed in the filaments which are joined to form large bundles. While their abundance is subject to variation, no case of a sponge with but a few isolated filaments is on record. No apparent young stages of these filaments have been seen. Schulze's researches enabled him to make no positive statement concerning them, but they at the same time demonstrated that "no cellulose is contained in them, that they have no trace of true cellular structure, and that they contain a great deal of nitrogen (9·2 per cent. of their substance), and that they are not Algæ. The resistance of the filaments in boiling alkali is against their being ordinary Fungi, while their general chemical composition indicates no relationship to the ordinary sponge skeleton." As to the very minute dumb-bell shaped structures observed by Poléjaeff, and considered by him to be young stages of the filaments, Lendenfeld thinks that this is extremely doubtful, "particularly as nobody besides Poléjaeff has seen them in *H. friabilis* or any other sponge." But is this so? for in another paragraph we read:—

"The spherical bodies which Schmidt and Poléjaeff consider as young stages of these filaments—in fact, as terminal knots, either dropped off, or on the way to produce a filament—have also been observed and carefully studied by Schulze, who considers them as monocellular Algæ, which have nothing whatever to do with the filaments."

Lendenfeld says that "no trace of filaments or 'spores' can be detected in the young embryos which are often found in specimens of Hircinia."

On the physiology of the group, this monograph throws but little light:—

"Our knowledge of the vital functions of sponges is at present exceedingly unsatisfactory. We do not even know which parts of the sponge absorb nourishment, or, in fact, what kind of food the sponges take in. We are equally ignorant concerning their respiration and secretion."

There being then no facts to serve us as guides to knowledge, the next "best thing" is to have recourse to imaginations, and our author "thinks" that "it is by no means unlikely that the sponges may exclusively absorb liquid food—that is to say, organic substances dissolved in the water which is continuously passing through their canal system. All the other organisms in which arrangements are made to insure a continuous water current—I refer to the higher plants—absorb exclusively nourishing material in solution (the absorption of gaseous food by plants does not concern us here). The existence of a traversing canal system and a continuous water current seems to me to point to the nourishing material of sponges being in solution in the sea-water. The numerous fine sieves and filter arrangements generally, and the mere fact that the water always enters through the smaller holes and is expelled through the larger, clearly shows that the sponges are not desirous that large food-particles should enter their canal system."

Even granting that the word "exclusively" should be after the word "material," we do not quite understand the comparison of the well-known facts of plant physiology as they are presented to us in the above extract, nor see how it helps us to an understanding of how the sponge adds to its protoplasm; the undoubted power possessed by some of the sponge-cells to lay down silica, lime, &c., is quite different functionally from the phenomena attending growth and development, using these terms in Herbert Spencer's sense; but once set a thinking, our author proceeds, and telling us that a "tape-worm is an animal which takes up liquid food, and which has no special digestive apparatus, and that it evidently takes up a great quantity of material from the surrounding chyle through the apparently indifferent cylindrical ectodermal epithelium cells; that the excess material and waste products are got rid of by the nephrydia," he goes on to say that he is inclined "to think that in sponges we may have a similar mode of absorption of nourishment"; but then, where are the nephrydia or their analogues? and he thinks again "that it is not impossible that the ciliated chambers may be partly analogous to the nephrydia of the Cœlomata, and that the collar-cells may, besides performing other functions, also secrete the urine." However uncertain, he adds, this hypothesis may appear, "I think there can be no doubt that there is more probability in it than in the view, held by Carter and others of the older authors, that the ciliated chambers are merely digestive apparatus." This seems a rather dreamy hypothesis, with no facts for its foundation; but it is but fair to remark that it comes at the very end of a volume which is a record of numerous and important observations.

Under the headings variability, parasitism, and symbiosis, many interesting details are given. The author thinks that certain forms of Aulena and Chalinopsilla imitate "certain siliciferous Cornacuspongiæ. These sponges have descended from those which they imitate; and, whilst they have lost the spicules in the fibres, they have retained the outer appearance of their better protected ancestors in a most striking manner." Apparently, "the primordial sponge ancestors were free-swimming, and had no skeleton. Some produced a calcareous, others a siliceous skeleton; in both the subsequent development, the formation of ciliated chambers, which the ancestors did not possess, and the fixing of the axis and rays of the spicules, were the same. The primordial Silicea had indifferent irregular spicules, from which the

triaxon and the tetraxon spicules were developed by an adaptation of the divergent development of the canal system.. The primordial forms of both lived in water rich in silica, and certain forms of both lost their spicules in consequence perhaps, of rising from deeper to shallower water, where silica is more scarce. In both, some forms have lost the skeleton altogether, while others have replaced it gradually by spongin."

While acknowledging that some authors whose opinions must carry great weight, such as Balfour, Bütschli, and Sollas, consider the sponges as a separate group, equal in value to the groups Protozoa and Metazoa, Lendenfeld cannot but conclude that the sponges are, without doubt, Metazoa, and certainly Cœlentera, in the sense of being provided with a simple body cavity.

The last twenty pages of the work are devoted to a synopsis of all the known sponges, giving the classes, families, orders, and genera. In this extremely useful list there is a short analysis of the families and orders, which is based on the labours of Vosmaer, Ridley, Dendy, Sollas, Schulze, added to those of the author's own. The author ends his treatise with the statement that "Now that all the groups of sponges have been thoroughly investigated, we may consider our knowledge of their phylogenetic affinities established on a satisfactory footing" (p. 909); but it seems well to call to mind the statement with which he closes his short preface, and with which we feel the more inclined to agree, "our present knowledge of the group . . . has only just arrived at a stage corresponding to the knowledge of the higher animals of half a century ago" (p. 5).

In concluding our only too brief notice of this important work, for which all workers on the group must thank Dr. Lendenfeld, we may mention that the sponge portraits are for the most part photo-lithographs taken from the original types; though in a few cases, where no good specimens were available, the lithographic illustrations are from drawings.

THE FLORA OF SUFFOLK.

The Flora of Suffolk. By W. M. Hind, LL.D., Rector of Honington, assisted by the late Churchill Babington, D.D., F.L.S. With a Chapter on the Geology, Climate, and Meteorology of Suffolk, by Wheelton Hind, M.D., F.R.C.S. Pp. 508, with a Map. (London: Gilbert and Jackson, 1889.)

SUFFOLK is a characteristic lowland maritime English county, the flora of which, at the present day, contains absolutely no infusion of the boreal element. Its area is about 1500 square miles. The whole surface is flat, without any prominent rocks. It is underlain by chalk, which, in the north and west, lies immediately below the subsoil, but, in the south and east, is covered by Tertiary and Glacial deposits, which at Harwich have been found to reach a thickness of 1000 feet before the chalk is reached. In White's history of the county, its soils are classified into three groups: heavy lands, in which clay predominates; mixed land, common mixed soil, rich deep moulds, fen-lands, and rich marshes; and light lands, consisting of sand over chalk. To the first set belong the soils of the western two-thirds of the county, except in the extreme north and near the coast. The mixed lands are found—one portion east of the heavy lands between the Orwell and the Stour; a second in the north, between Halesworth and Yarmouth; and a third west of the heavy lands between Holston and Newmarket. The sandy, or light, soils are in the extreme north-west, in what is called the "Breck district," between Thetford and Mildenhall, where are found the rarest plants of the county, such as *Veronica hybrida*, *V. triphyllos*, *V. verna*, and *Apera interrupta*. The coast is remarkable for the extent of its tidal estuaries and bays, creeks and havens. There are no cliffs of any considerable height, but a great extent of sand and shingle. The beach at Orford, where grows the great mass of *Lathyrus maritimus*, the seeds of which saved the life of many poor people in a famine in the middle of the sixteenth century, is said to have the greatest breadth of sand anywhere on the English coast. The rivers are shallow streams with slow currents. In the north-east there are several lakes of brackish water, not so well known as the Norfolk Broads, of which Braydon Water covers 1200, and Thorpe Mere 1000, acres. The fresh-water lakes of the county are few and small. There is a considerable area of fen- and marsh-land, both in the north-west and east, so that we get in the county all the conditions that produce a rich low-country flora, and, superadded to the common lowland plants, rarities characteristic of chalk country, the seashore, and fen-land ditches and marshes.

The country is so easy of access from the centres where have lived many of the best botanists of bygone time, such as London, Cambridge, Yarmouth, Norwich, and Saffron Walden, that the principal features of its botany have long been known, and many excellent botanists, from the time of Buddle down to the present day, have resided within its compass. The father of Suffolk botany was Sir John Cullum, F.R.S., who lived near Bury St. Edmunds, and kept a diary between 1772 and 1785, in which he has recorded the occurrence of upwards of 500 plants. To his son, Sir Thomas Cullum, F.R.S., who was also an enthusiastic botanist, Sir J. E. Smith dedicated his "English Flora." In the present work there is not only a full general history of the progress of Suffolk botany, but, under each plant, the name of its first known collector is registered. The first "Flora" of the county was published in 1860. It was carried out mainly by the exertions of the late Mr. E. Skepper, working under the superintendence of Prof. Henslow. After it was published, Mr. Skepper made a great many notes for a new edition, but he died in 1867. For several years the Rev. Churchill Babington, who settled in the county in 1866, paid attention to the subject. In 1875, the Rev. W. M. Hind, a very competent botanist, well known by his "Flora of Harrow," settled in the county, and Dr. Babington sought and obtained his assistance to carry on the work. Dr. Babington died early in the present year.

The bulk of the book is, of course, occupied by the enumeration of the species and an account of the distribution and special localities of the varieties. The county is divided into five districts, and the distribution of the plants is traced through them. Only the Phanerogamia and Vascular Cryptogamia are dealt with, but the mosses of the county have also been well worked.

There is also a detailed tabular comparison of the plants of Suffolk with those of Norfolk, Cambridgeshire, and Essex, and a short chapter on the characteristic plants of the different soils of the county, which will be found very interesting to students of plant-dispersion. The chapters contributed by Dr. Wheeler Hind, the son of the editor, on the geology, physical geography, and meteorology of the county are very full, clear, and add greatly to the interest of the book.

One of the most interesting circumstances in the county flora is the occurrence of several maritime plants far inland. In the Breck country, between Thetford and Mildenhall, grow *Vicia lutea*, *Erythræa littoralis*, *Rumex maritimus*, *Carex arenaria*, *Phleum arenarium*, and *Corynephorus canescens*. These are all seaside plants, and their occurrence fifty miles inland is accounted for by Prof. Newton and the editor by supposing that an arm of the sea has penetrated here southward from the Wash at a comparatively recent period.

It is in Norfolk and Suffolk that the most valuable observations have been made, by Mr. Clement Reid and his fellow-workers, in illustration of the time of origin of our present British flora. The Cromer plant-bed extends into Suffolk, past Pakefield, to Southwold and Dunwich. This is pre-glacial, and yet, out of upwards of forty plants found in it that have been clearly identified, there are only two that are not British now—the spruce fir and *Trapa natans*. At Hoxne, near Diss, lacustrine deposits have been found resting on a bed of boulder clay, but beneath beds which contain bones of the elephant. In these are contained *Salix polaris*, *S. Myrsinites*, *Betula nana*, *Hypnum sarmentosum*, and a *Pinus* which is probably *sylvestris*—all characteristic Arctic-Alpine types, associated with many lowland plants which grow unchanged in Suffolk at the present time. A chapter in the book contains a list of all these plants, but their geological position is not clearly explained.

It will be seen that this is a very interesting and complete county flora, and that it is worthy of being studied carefully by all who are interested in the distribution of our indigenous plants. J. G. B.

THE MANUFACTURE OF IRON AND STEEL.

Iron and Steel Manufacture. By Arthur H. Hiorns. (London: Macmillan and Co., 1889.)

THIS volume is meant as a text-book for beginners, and will very worthily occupy that position. It is full of information, and information of the very kind which the student should possess before entering upon the study of the greater works of Percy or Phillips. On the other hand, those already engaged in the metallurgy of iron and steel will find in these pages much that may be referred to.

The book begins with a brief history of the processes that have been employed down to our own time, the landmarks in which are Dud Dudley's successful attempts to smelt with coal at the beginning of the seventeenth century; Cort's introduction of the puddling process in 1784; Neilson's recommendation to use hot blast in 1828; the revolution produced in the iron trade by the invention of the Bessemer steel process in 1855, as supplemented by R. F. Mushet, of the Siemens furnace and steel process, and finally of Thomas and Gilchrist's basic process.

The chapter which deals with chemical principles and changes, inserted for the benefit of those having a limited knowledge of chemistry, is valuable on account of the simple manner in which it is written; this is particularly the case as regards oxidizing and reducing agents, the examples given of oxidation and reduction showing the reactions very clearly. A chapter is devoted to the definition of metallurgical terms, refractory materials and fuel, another to the ores and alloys of iron, and then a description of the various processes employed in the metallurgy of iron and steel is given, attention being pretty equally divided between the two metals.

The most ancient and most difficult method of extracting iron from the ore is what is known as the direct method, and the author explains clearly the two causes of its failure, whether in the case of the old Catalan or any of the modern processes, and the reason why the blast furnace, although an indirect, has proved so successful a method. These two causes are "the easy oxidation of iron by carbonic acid and water, at the temperature at which ferrous oxide is reduced to the metallic state by carbon, carbonic oxide, or hydrogen, and the facility with which iron at a red heat combines with carbon."

The preparation of the ores for reduction in the blast furnace and their treatment therein are next brought forward, the advantages and disadvantages of the hot blast, the utilization of waste gases, the dimensions and form of blast furnace and subsidiary subjects being treated of.

The metal being now in the state of pig-iron, the means of refining and puddling are described; the various arrangements are set forth by which attempts have been made to effect the work of the puddler by mechanical means, whether by automatic rabbles or rotatory furnaces, and their relative advantages and disadvantages. A chapter is devoted to the treatment of puddled iron under the hammer and in the rolling mill, and to the tinning and galvanizing of iron.

Leaving the subject of malleable iron, the author next considers the question of iron-founding. He describes the cupola furnace in which the pig metal is fused; and the various methods of moulding and casting, and the brands of pig-iron used for different purposes, are treated of.

About a third of the book is devoted to the consideration of steel; it is in this branch of the treatment of iron that the greatest development has occurred of late years, and the book under review treats of all the modern practice. It is pleasant to find, too, in the preparation of an elementary work, that constructive perspective has been employed. Modern processes are not brought into prominence simply because they are modern, and ancient methods are not thrown into the shade if still employed. Amongst the latter we find full attention given to the cementation process, and crucible steel; whilst a chapter is devoted to each of the processes of Bessemer and Siemens. The book finishes with a chapter on steel-casting and on testing.

The volume before us is intended to assist pupils preparing for the ordinary grade examinations of the City and Guilds of London Institute, and its author—the principal of the School of Metallurgy in connection with

the Birmingham and Midland Institute—is to be congratulated on the good work he has done in this connection. The book is illustrated with 72 figures, which agree with the simplicity and clearness of the diction, and questions are found at the end of each chapter, which have been well prepared to test the learner's apprehension of its contents. We are pleased to be able to recommend this little work, as a foundation for the study of the metallurgy of iron and steel.

OUR BOOK SHELF.

On the Creation and Physical Structure of the Earth. By J. T. Harrison, F.G.S., M.Inst.C.E. (London: Longmans, 1889.)

THIS book brings to mind one of the most winning of the vagaries of childhood. A bright child of an inquiring turn will sometimes sit with comical sedateness listening to the talk of its elders. It may afterwards be overheard repeating to one of its playmates, or to some lucky adult who has the knack of winning its confidence, such detached scraps of the conversation as have found a resting-place in its little brain; and, conscious even at its early age of the necessity of some continuity in a narrative, filling up the gaps with inventions or criticisms of its own, charming every way, but mainly on account of their utter want of connection with the subject of the conversation which it is attempting to report. So our author has listened to the teaching of many geologists, and has culled many detached passages from their writings: these he repeats to the world in a book, printing between them comments and lucubrations of his own, about as innocent and as little apposite as the child's prattle—hardly so amusing, however. The following passage is a fair sample of the writer's own share in the book. "The termination of the Secondary Period, which introduced these altered conditions of the surface of the northern hemisphere, was really the commencement of what is called the Glacial epoch in Europe. We have noted signs of glaciation during the deposition of the upper chalk in India and North America, but now the conditions which induced that glaciation are extended in such a manner as to unite these districts, and produce that enormous accumulation of snow and ice at the North Pole, the weight of which in the Miocene epoch depressed the crust in that region and upheaved the mighty mountain ranges to which I have just referred."

The book bristles with cataclysms and catastrophes. The shifting of a thin crust on an internal nucleus which it does not fit, and incessant protrusions of granite, are invoked to account for phenomena which every-day people still persist in thinking are satisfactorily explained by every-day causes. But the author is one born out of due time—two centuries too late. How he and Burnet would have enjoyed a crack together! But there is this to be said, the "Sacred Theory of the Earth" is Burnet's own: the staple of the present work consists of extracts from the works of others. The mottoes are verses from the first chapter of Genesis, but their relevancy to the subject-matter of the chapters which they head is not obvious. A. H. G.

Through Atolls and Islands in the Great South Sea. By F. J. Moss. (London: Sampson Low, 1889.)

MR. MOSS—a member of the House of Representatives, New Zealand—started from Auckland, in September 1886, in the schooner *Buster*, for a voyage among the islands and islets of "the outer lagoon world." He was absent seven months, and during that period he crossed the equator six times, and visited more than forty islands among the least frequented groups. In the present volume he sums up the impressions produced upon him by what he saw and heard in the course of his voyage. Mr. Moss, in dealing with matters which really interest him, shows that he is an accurate observer and a man of sound judgment. His style, although plain and unpretending, is well fitted for the task he has fulfilled. The best parts of the book are those in which he tries to convey some idea of the daily life led by those natives whose customs he had an opportunity of studying. He appreciates warmly some aspects of the various Polynesian types of character, but thinks that the people are likely to degenerate rapidly, unless they can be provided with a better class of native teachers than most of those to whom the duty of guiding them is now intrusted. What is needed, he thinks, is, that the islanders shall have in their work and in their amusements freer scope for the imaginative powers with which they are endowed, and the exercise of which is too often foolishly discouraged. Everything Mr. Moss has to say on this subject deserves the serious consideration of those to whom his warnings and counsels are either directly or indirectly addressed.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Who Discovered the Teeth in Ornithorhynchus?

IN NATURE of November 14 (p. 31), Profs. Flower and Latter criticise my note which appeared the week previous (November 7, p. 11), concerning the discovery of teeth in the young *Ornithorhynchus*. They promptly dismiss my claim that Sir Everard Home discovered the teeth of the young *Ornithorhynchus*, by stating that the structures described and figured by Sir Everard are the well-known cornules of the adult animal.

If they will take the trouble to turn to the plate cited by me—namely, Plate lix. of the second volume of Home's "Lectures," 1814—and will read the accompanying explanation, they will see that Home was familiar with the teeth of both the young and the old animal.

For the benefit of those who may not have access to Home's "Lectures," I here reproduce outline tracings of two of his figures. Plate lix. Fig. 2, shows the teeth of the *young Ornithorhynchus*—the "first set," as Home says, "to show that there are two grinding teeth on each side." The next figure is a similar tracing from the succeeding plate in Home's "Lectures" (Plate lx.), which represents, to again use Home's words, "the under jaw of the full-grown *Ornithorhynchus paradoxus*, to show that there is only one grinder on each side." Both of these figures are natural size.

In the face of these *facts*, further comment seems unnecessary.

I admit, of course, that Home did not discover the chemical composition of the teeth of the young animal—this was Poulton's discovery. C. HART MERRIAM.

Washington, D.C., November 30.

[We do not reproduce the outlines sent, as anyone interested in the subject may see the originals, not only in Home's "Comparative Anatomy," but in the Philosophical Transactions, where they first appeared.—ED. NATURE.]

I SHOULD be very sorry to deny the credit of any discovery to Sir Everard Home, or anyone else, if any evidence could be shown of its having been made. Of the figures cited by Dr. Hart Merriam, that of the younger animal seems (as far as can be judged from the roughly executed engraving, with the assistance of the descriptive text) to represent the horny plates, showing the hollows from which the true teeth have recently fallen; that of the old specimen, the same plates after they are fully grown, and their surfaces worn down by attrition. This difference led Home to conjecture that these plates were changed during the growth of the animal—a view which was corrected by Owen ("Comp. Anat. of Vertebrates," vol. iii. p. 272), by the statement

that "each division or tubercle of the [horny] molar is separately developed, and they become confluent in the course of growth." By the way, no one can have been better acquainted with the work of Home than his successor in the Hunterian Chair, Sir Richard Owen; and yet, in his numerous references to this subject (Art. "Monotremata," "Cyclop. Anat. and Physiology"; "Odontography"; "Comp. Anat. of Vertebrates," &c.), no trace is shown of any knowledge of a discovery which could not have failed to have interested him, if it had been made before his time.

If a cursory perusal of Sir Everard Home's first account of the mouth of the Ornithorhynchus (in the Philosophical Transactions for 1800), or any interpretation placed upon his figures, might lead anyone to infer, with Dr. Merriam, that the real teeth of the young animal had been discovered at that time, the best possible authority may be conclusively cited against such an idea, no other than that of Home himself, who, in his later description of the same specimen ("Lectures on Comparative Anatomy," 1814), describes the organs in question as "the first set of *cuticular teeth*"—an expression quite incompatible with their being the teeth described by Mr. Poulton and Mr. Oldfield Thomas. It really seems superfluous to have to remind a zoologist of such high repute as Dr. Hart Merriam that the difference between teeth with the structure and mode of growth which characterize these organs in the Mammalia generally, and the horny epithelial plates of Ornithorhynchus, is not merely one of "chemical composition." W. H. FLOWER.

The Pigment of the Touraco and the Tree Porcupine.

ATTENTION has been lately again directed to the red pigment in the wing feathers of the touraco, which has been stated by several observers to be soluble in pure water. Prof. Church, who was the first to experiment upon this pigment (*The Student*, vol. i., 1868; *Phil. Trans.*, 1869), quotes Mr. Tegetmeier and others, to the effect that this pigment can be washed out of the feathers by water. Later, M. Verreaux (Proc. Zool. Soc., 1871) confirmed these statements from his own experiments while travelling in South Africa; attempting to catch one of these birds whose feathers were sodden with rain, he found that the colour stained his hands "blood-red." A few years ago Prof. Krukenberg ("Vergl. Phys. Studien") took up the study of turacin—as Prof. Church termed the pigment—and added some details of importance to Prof. Church's account; Krukenberg, however, contradicted certain of the statements quoted by Church with reference to the solubility of turacin in pure water, remarking that the pigment in the dead bird is insoluble in water. A writer in the *Standard* of October 17 is able "partially to confirm" the assertion that turacin is soluble in pure water. Seeing that there is some conflict of opinion with regard to this matter, I think it worth while to state that I found it quite easy to extract with tap water (warm) some of the pigment from a spirit-preserved specimen of the bird; only a very small amount could be extracted in this way, and the feathers were not perceptibly decolorized even after remaining in the water for a fortnight. I also experimented upon a feather just shed from one of the specimens now in the Zoological Society's Gardens; this was steeped in water for some time without any effect being visible, but after a period of two days the water became stained a very faint pink.

The touraco, however, is not a unique instance of a terrestrial animal with an external colouring matter soluble in water. I am not aware whether other cases have been recorded, but I find a pigment of a similar kind in a South American tree porcupine (*Sphingurus villosus*).

This porcupine has bright yellow spines which are for the most part concealed by abundant long hair. The spines themselves are parti-coloured, the greater part being tinged with a vivid yellow; the tip is blackish-brown. I was unable to extract this pigment with chloroform, or with absolute alcohol even when heated; like so many other colouring substances which are insoluble in these fluids, the pigment could be extracted by potash or ammonia; I found also that tap water, warm or cold, dissolved out the yellow colour; the action was slower than when the water was first rendered alkaline by the addition of ammonia, but, unlike the touraco, the pigment was nearly, if not quite, as completely dissolved. The skin, from which the spines were taken, was a dried skin of an animal recently living in the Zoological Society's Gardens; it had not been preserved in alcohol or treated in any way which might lead to the supposition that the pigment was chemically altered. There is, therefore, a considerable probability that in the living animal the pigment is also soluble in water. I believe that this yellow pigment is undescribed, but I have not yet completed my study of it; in any case, it is not zoofulvin or picifulvin, or any "lipochrome." FRANK E. BEDDARD.

Exact Thermometry.

IN the account which Prof. Mills has given (NATURE, December 5, p. 100) of M. Guillaume's "Traité pratique de la Thermométrie de précision," the permanent ascent of the zero-point of a mercurial thermometer, after prolonged heating to a high temperature, is stated to be due to compression of the bulb—rendered more plastic by the high temperature—by the external atmospheric pressure.

The constant slow rise of the zero-point of a thermometer at the ordinary temperature is mentioned by Prof. Mills; and the late Dr. Joule's observation of this change in a thermometer during twenty-seven years is specially alluded to. It may, I imagine, be taken for granted that after the lapse of a sufficient length of time—possibly many centuries—a final state of equilibrium would be attained; and it has always appeared to me that the effect of heating the thermometer to a high temperature is simply to increase the rate at which this final state is approached. It is my impression that, owing to the more rapid cooling of the outer parts of the bulb after it has been blown, the inner parts are in a state of tension, as, to a very exaggerated degree, in the Prince Rupert's drops; and that it is the gradual equalization of the tension throughout the glass that causes the contraction; in other words, that the process is one of slow annealing.

This explanation appears to be supported by the facts—(1) that when a thermometer is exposed for a long time to a high temperature, the zero-point rises rapidly at first, then more and more slowly, and finally becomes constant or nearly so; (2) that the higher the temperature the more rapidly is this state of equilibrium attained. I do not know of any experimental evidence that the rate of ascent is influenced by changes of external pressure, and it seemed to be desirable to test the point.

In order to do this I have exposed three thermometers, A, B, and C, constructed by the same maker and of the same kind of glass, to a temperature of about 280° for several days in the same vapour-bath, under the following conditions:—The thermometers were all placed in glass tubes closed at the bottom (C being suspended from above), and the tubes were heated by the vapour of boiling bromonaphthalene. One of the tubes—that containing thermometer C—was exhausted so as to reduce the external pressure on the bulb to zero; the others were open to the air. In thermometer A there was a vacuum over the mercury, but air was admitted into B and C to increase the internal pressure. Consequently, the bulb of A was exposed to a resultant external pressure equal to the difference between the barometric pressure and that of the column of mercury in the stem of the thermometer; the internal and external pressures on the bulb of B were approximately equal; lastly, the internal pressure on the bulb of C was the sum of the pressures of the column of mercury in the stem and of the air above it, while the external pressure was zero.

The following results were obtained:—

	A.	Rise.	B.	Rise.	C.	Rise.
Zero before heating ...	0·15		0·10		−0·10	
		0·35		0·25		0·40
After 2 hours' heating ...	0·50		0·35		0·30	
		0·80		0·75		0·80
After an additional 5½ hours' heating	1·30		1·10		1·10	
Total rise of zero-point...		1·15		1·00		1·20

The thermometers were heated until 5 p.m. each day, and the zero-points read on the following morning.

If the diminution of volume of the thermometer bulb, usually observed, were due to external pressure, the zero-point of A should have risen, that of B should have remained nearly stationary, while that of C should have fallen. Instead of this, however, the zero-points of all three thermometers rose at nearly the same rate; therefore the yielding of the bulbs to pressure, owing to the plasticity of the glass, if it occurred at all, had no sensible effect on the result. SYDNEY YOUNG.

University College, Bristol, December 12.

Locusts in the Red Sea.

A GREAT flight of locusts passed over the s.s. *Golconda* on November 25, 1889, when she was off the Great Hanish Islands in the Red Sea, in lat. 13°·56 N., and long. 42°·30 E.

The particulars of the flight may be worthy of record.

It was first seen crossing the sun's disk at about 11 a.m. as a dense white flocculent mass, travelling towards the north-east at about the rate of twelve miles an hour. It was observed at noon by the officer on watch as passing the sun in the same state of density and with equal speed, and so continued till after 2 p.m.

The flight took place at so high an altitude that it was only visible when the locusts were between the eye of the observer and the sun; but the flight must have continued a long time after 2 p.m., as numerous stragglers fell on board the ship as late as 6 p.m.

The course of flight was across the bow of the ship, which at the time was directed about 17° west of north, and the flight was evidently directed from the African to the Arabian shore of the Red Sea.

The steamship was travelling at the rate of thirteen miles an hour, and, supposing the host of insects to have taken only four hours in passing, it must have been about 2000 square miles in extent.

Some of us on board amused ourselves with the calculation that, if the length and breadth of the swarm were forty-eight miles, its thickness half a mile, its density 144 locusts to a cubic foot, and the weight of each locust $\frac{1}{16}$ of an ounce, then it would have covered an area of 2304 square miles; the number of insects would have been 24,420 billions; the weight of the mass 42,580, millions of tons; and our good ship of 6000 tons burden would have had to make 7,000,000 voyages to carry this great host of locusts, even if packed together 111 times more closely than they were flying.

Mr. J. Wilson, the chief officer of the *Golconda*, permits me to say that he quite agrees with me in the statement of the facts given above. He also states that on the following morning another flight was seen going in the same north-easterly direction from 4.15 a.m. to 5 a.m. It was apparently a stronger brood and more closely packed, and appeared like a heavy black cloud on the horizon.

The locusts were of a red colour, were about $2\frac{1}{2}$ inches long, and $\frac{1}{16}$ of an ounce in weight. G. T. CARRUTHERS.

A Marine Millipede.

IT may interest "D. W. T." (NATURE, December 5, p. 104) to know that *Geophilus maritimus* is found under stones and sea-weeds on the shore at or near Plymouth, and recorded in my "Fauna of Devon," Section "Myriopoda," &c., 1874, published in the Transactions of the Devonshire Association for the Advancement of Literature, Science, and Art, 1874. This species was not known to Mr. Newport when his monograph was written (Linn. Trans., vol. xix., 1845). Dr. Leach has given a very good figure of this species in the *Zoological Miscellany*, vol. iii. pl. 140, Figs. 1 and 2, and says: "Habitat in Britannia inter scopulos ad littora maris vulgatissime." But, so far as my observations go, I should say it is a rare species. See *Zoologist*, 1866, p. 7, for further observations on this animal. EDWARD PARFITT.

Exeter, December 9, 1889.

Proof of the Parallelogram of Forces.

THE objection to Duchayla's proof of the "parallelogram of forces" is, I suppose, admitted by all mathematicians. To base the fundamental principle of the equilibrium of a *particle* on the "transmissibility of force," and thus to introduce the conception of a *rigid body*, is certainly the reverse of logical procedure. The substitute for this proof which finds most favour with modern writers is, of course, that depending on the "parallelogram of accelerations." But this is open to almost as serious objections as the other. For it introduces kinetic ideas which are really nowhere again used in statics. I should therefore propose the following proof, which depends on very elementary geometrical propositions. The general order of argument resembles that of Laplace.

I adopt the "triangular" instead of the "parallelogrammic" form. Thus, if PQ, QR represent in length and direction any directed magnitudes whatever, and, *if these have a single equivalent*, that single equivalent will be represented by PR.

To prove that the equivalent of PQ, QR is PR.

(1) The equivalent of two perpendicular lengths is equal *in length* to their hypothenuse.

For, draw AD perpendicular to hypothenuse BC.

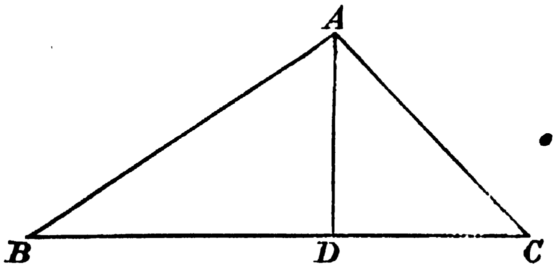

FIG. 1.

Then, let BD, DA $= k$. BA, making angle θ with BA towards BD.

Then, by similar triangles, AD, DC $= k$. AC, making angle θ with AC towards AD.

But these equivalents are at right angles, and proportional to BA and AC. Hence, their equivalent, by similar triangles, is k^2 . BC along BC.

But BD, DA, AD, DC = BC. $\therefore\ k^2 = 1$; $\therefore\ k = 1$.

(2) If theorem holds for right-angled triangle containing angle θ, it holds for right-angled triangle containing $\frac{1}{2}\theta$.

For, let ACD $= \theta$, where D is 90°. Produce DC to B, such that CB = CA. Then ABD $= \frac{1}{2}\theta$.

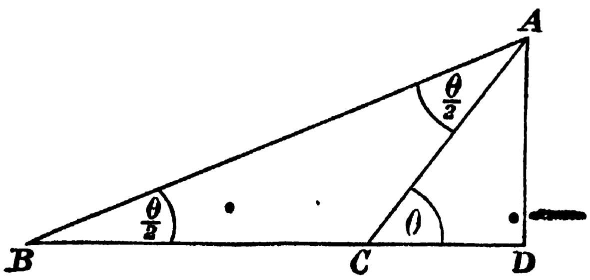

FIG. 2.

Then assume CD, DA = CA. Add BC. $\therefore$ BD, DA = BC, CA.

But BD, DA = BA in magnitude by (1); and BC, CA has its equivalent *along* BA, $\because$ BC = CA. $\therefore$ BD, DA = BA, both in magnitude and direction.

(3) If the theorem holds for θ and ϕ, it holds for $\theta + \phi$.

For make the well-known projection construction. Thus—

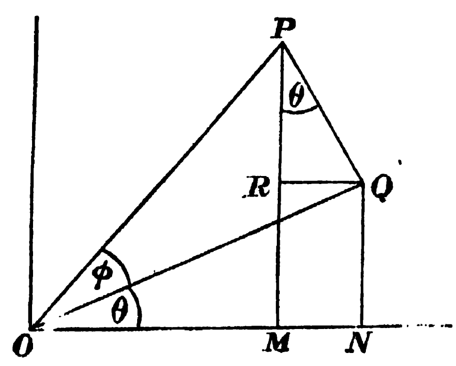

FIG. 3.

$$OP = OQ,\ QP = ON,\ NQ,\ QR,\ RP = OM,\ MP.$$

(4) Finally, by (1), theorem holds for isosceles right-angled triangle; $\therefore$ by (2) it holds for right-angled triangle containing angle $90° \div 2^n$; $\therefore$ by (3) it holds for right-angled triangle containing angle $m.\ 90° \div 2^n$: *i.e.* for *any* angle (as may be shown, if considered necessary, by the method for incommensurables in Duchayla's proof).

Hence, if AD be perpendicular on BC in *any* triangle,

$$BA,\ AC = BD,\ DA,\ AD,\ DC = BC. \qquad \text{Q.E.D.}$$

W. E. JOHNSON.

Glories.

MR. JAMES MCCONNEL asks in NATURE (vol. xl. p. 594) for acccounts of the colours and angular dimensions of glories. I saw a good instance of the phenomenon on Lake Superior, June 17, 1888, and, having had my attention called to the value of accurate descriptions in such cases by Mr. Henry Sharpe's "Brocken Spectres," I examined it carefully.

The shadow of my head on the mist was surrounded by a brilliant halo or glory, slaty-white around the head, followed by orange and red; then a circle of blue, green, and red, and the same colours repeated more faintly. The diameter of the innermost and brightest circle of red, as measured on the graduated semicircle of a clinometer, was $4\frac{1}{2}°$. There was also a very distinct, but nearly white, fog-bow outside, of 42° radius, as measured in the same way.

A. P. COLEMAN.

Fossil Rhizocarps.

REFERRING to Sir William Dawson's note on this subject in NATURE of November 7 (p. 10), we regret that we have been unable to trace the original source from which the statement in our "Hand-book of Cryptogamic Botany" was derived, relative to the fructification of *Protosalvinia* or *Sporangites*. The sentence will therefore, with apologies to Sir W. Dawson, be removed from future editions of the work.

ALFRED W. BENNETT.

The Arc-Light.

WOULD you or any of your readers kindly tell me where I may find an account of any of the latest methods of determining the back E.M.F. of the arc-light?

JOSEPH MCGRATH.

Mount Sidney, Wellington Place, Dublin.

THE HYDERABAD CHLOROFORM COMMISSION.

THE appointment of a Commission at the present time to investigate the action of chloroform as an anæsthetic might to many seem an anomaly. For the use of chloroform as an anæsthetic was introduced over forty years ago: it was in November, 1847, that Prof. Simpson, of Edinburgh, first brought this valuable agent before the medical profession. Since that time, the use of chloroform has enormously extended, especially in our country, and although there are other valuable agents of the same class—such as ether and nitrous-oxide gas—yet there is a universality of opinion that the employment of chloroform has in many cases a special advantage. Considering the extensive use of the agent, and the progress which has been made of late years in the study of the action of drugs in man, it certainly is surprising that the knowledge of the effect of chloroform on the different parts and organs of the body is not complete. This is not altogether from want of attention to the subject; because, previous to the Hyderabad Commission, at least two Commissions were appointed with the view of investigating the action of chloroform and its occasional serious effects. These Commissions were appointed by the Royal Medical and Chirurgical Society of London, and by the British Medical Association, and they were composed of men who, from their knowledge of experiment and acquaintance with practical medicine, were competent to discuss the question. The two Commissions arrived at the same conclusions as the distinguished French man of science, Claude Bernard, had published years before, and these conclusions tallied with the teaching of the great London medical schools.

Chloroform and other anæsthetic agents have a peculiar position: they are powerful drugs used, not for disease itself, but for the purpose of allowing an operation to be performed, preventing the pain which would otherwise be felt, and relaxing the contraction and spasms of the muscles, so that the surgeon can more readily and accurately operate. The administration of the anæsthetic is something, then, outside the diseased condition; so that its use ought theoretically to be perfectly harmless to the sick person. Unfortunately it is not always so, and deaths from chloroform are, although rare, by no means unknown. The administrator of chloroform is therefore a person of great responsibility: he has to watch carefully the effect of the agent on the patient, to notice any unfavourable change that occurs, and to adopt measures to counteract any bad effects which appear. The knowledge of the mode in which chloroform causes danger to the life of the patient is therefore of vast importance; for, if the administrator knows the signs of danger, there is more likelihood of counteracting a fatal result. These fatal results, which are among the saddest that occur in medical practice, ought, if possible, to be avoided.

What, then, is the danger to life of chloroform? Or, to speak more fully, what particular part of the body does chloroform injuriously affect when there is danger? This is just the point that the various Commissions have attempted to settle. In the Scotch schools, more especially that of Edinburgh, it has been taught that the great danger of chloroform was in failure of respiration; meaning by this that the danger-signal of chloroform was the stoppage or irregularity of the breathing. As a corollary to this belief, it was considered that the heart was only affected after the breathing had become interfered with; that, in fact, the respiration stopping, the blood was not oxygenated, so the heart stopped beating. This was the teaching of the great Edinburgh surgeon, Syme. The English (and especially the London) teaching was almost directly opposed to this. It was taught, and is still taught in the London schools, that the great danger from chloroform arose from its effect on the heart, which stopped beating before the respiration ceased. Which, then, of these two doctrines is true, or are both true?

The decision of this question is, as we have stated, one of vast importance; but it must be remembered that, whichever is right, the administrator of anæsthetics always pays attention to both the beating of the heart and the regularity of the respiration. Surgeon-Major Lawrie, one of the prominent members of the Hyderabad Chloroform Commission, says that "it is possible to avert all risk to the heart by devoting the entire attention to the respiration during chloroform administration." Medical opinion in England, both of that of experts (professional anæsthetists) and of the general profession, is distinctly opposed to this view; and the administrator who does not attend to the pulse, as well as to the breathing, is certainly neglecting one of the main paths by which Nature shows us what is going on inside the organism.

From the statement of Surgeon-Major Lawrie just quoted, it will be seen that the Hyderabad Chloroform Commission came to the conclusion that the danger from the administration arose, not from the heart, but from the respiration. This view was strongly combated in our contemporary, the *Lancet*. The importance of the question led the Nizam of Hyderabad to obtain the services of a scientific medical man from England to go out to India and attempt to settle the question. Dr. Lauder Brunton, F.R.S., consented to go; and, well known as he is for his life-long devotion to the experimental investigation of the action of remedies and their practical application, it was considered probable that his aid in the research would lead to interesting and important results. From the somewhat scanty news of the results which have been telegraphed to England, it seems likely that the investigation now progressing at Hyderabad will tend to revolutionize existing views as to the action of chloroform.

Dr. Brunton's views as regards the dangers of chloroform before he left England were clearly expressed in his well-known "Text-book of Pharmacology." In it he says that "the dangers resulting from the employment of

chloroform are death by stoppage of respiration and death by stoppage of the heart;" he lays as much stress on the effect on the heart as on the respiration, and he proceeds to affirm that too strong chloroform vapour may very quickly paralyze the heart. This view is, indeed, similar to the one we have already mentioned as taught in the London schools of medicine. It is also well known that death may occur soon after chloroform has begun to be administered, from the heart being affected. If the operation is begun too soon, fainting from pain may supervene, and a fatal result occur: this has always been strongly insisted upon by Dr. Brunton. Surgeon-Major Lawrie says that in such cases it is not the chloroform that acts on the heart, but simply that there is fatal syncope or fainting.

From the large number of experiments on animals which Dr. Brunton has performed in India, in conjunction with the Hyderabad Commission and a medical delegate of the Indian Government, it appears that the "danger from chloroform is asphyxia or an overdose;" there is none whatever from the heart direct. This statement is a distinct reversal of the view generally held in England. It means that chloroform causes a fatal result by affecting the respiration or by too much being taken into the system and affecting the brain; and that there is no direct paralysis of the heart from the chloroform. A perfectly impartial opinion cannot, however, be formed from the scanty records of the investigation which have been as yet received in England. We must wait for fuller details of the experiments before a final judgment can be passed.

It is well, however, to point out that the prevailing view in England has been founded, not only on experiments on the lower animals, but also on the extended clinical observation of two generations of medical men. Clinical observation is not so accurate or so lucid as that of direct experiment, but it has its value, and one by no means to be despised in a case where it is so extensive, and directed to a subject of such great importance, not only to the medical profession, but to the general public, as the question of the administration of chloroform.

ON THE CAVENDISH EXPERIMENT.

In the last number of the Proceedings of the Royal Society (vol. xlvi. p. 253), I have given an account of the improvements that I have made in the apparatus of Cavendish for measuring the constant of gravitation. As the principles and some of the details there set out apply very generally to other experiments where extremely minute forces have to be measured, it is possible that an abstract of this paper may be of sufficient interest to find a place in the columns of NATURE.

In the original experiment of Cavendish (Phil. Trans., 1798, p. 469), as is well known, a pair of small masses, *m m* (Fig. 1), carried at the two ends of a very long but light torsion rod, are attracted towards a pair of large masses, M M, thus deflecting the arm until the torsion of the suspending wire gives rise to a moment equal to that due to the attraction. The large masses are then placed on the other side of the small ones, as shown by the dotted circles, and the new position of rest of the torsion arm is determined. Half the angle between the two positions of rest is the deflection produced by the attracting masses. The actual force which must be applied to the balls to produce this deflection, can be directly determined in dynamical units when the period of oscillation and the dimensions and masses of the moving parts are known. In the original experiment of Cavendish, the arm is 6 feet long, the little masses are balls of lead 2 inches in diameter, and large ones are lead balls 1 foot in diameter. Since the attraction of the whole earth on the smaller balls only produces their weight, *i.e.* the force with which they are attracted downwards, it is evident that the balls, M M, which are insignificant in comparison with the size of the earth, can only exert an extremely feeble attraction. So small is this that it can only be detected when the beam is entirely inclosed in a case to protect it from draughts; when, further, the whole apparatus is placed in a room into which no one must enter, because the heat of the body would warm the case unevenly, and so set up air currents which would have far more influence than the whole attraction to be measured; and when, finally, the period of oscillation is made very great, as, for instance, five to fifteen minutes. In order to realize how small must be the force that will only just produce an observable displacement of the balls, *m m*, it is sufficient to remember that the force which brings them back to their position of rest is the same as the corresponding force in the case of a pendulum which swings at the same rate. Now a pendulum that would swing backwards and forwards in five minutes would have to be about 20,000 metres long, so that in this case a deflection of one millimetre would be produced by a force equal to 1/20,000,000 of the weight of the bob. In the case of a pendulum swinging backwards and forwards once in fifteen minutes the corresponding force would be nine times as small, or 1/180,000,000 of the weight.

In spite of the very small value of the constant of gravitation, Cavendish was able, by making the apparatus on this enormous scale, to obtain a couple which

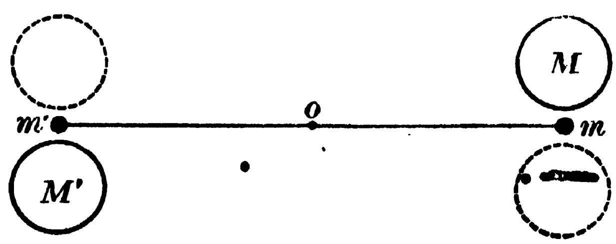

FIG. 1.

would produce a definite deflection against the torsion of his suspending wire.

These measures were repeated by Reich (*Comptes rendus*, 1837, p. 697), and then by Baily (*Phil. Mag.*, 1842, vol. xxi. p. 111), who did not in any important particular improve upon the apparatus of Cavendish, except in the use of a mirror for observing the movements of the beam.

Cornu and Baille (*Comptes rendus*, vol. lxxvi. p. 954, vol. lxxxvi. pp. 571, 699, 1001) have modified the apparatus with satisfactory results. In the first place they have reduced the dimensions of all the parts to about one-quarter of the original amount. Their beam, an aluminium tube, is only ½ metre long, and it carries at its ends masses of ¼ pound each, instead of about 2 pounds, as used by Cavendish. This reduction of the dimensions to about one-quarter of those used previously is considered by them to be one of the advantages of their apparatus, because, as they say, in apparatus geometrically similar, if the period of oscillation is unchanged, the sensibility is independent of the mass of the suspended balls, and *is inversely as the linear dimensions*. I do not quite follow this, because, as I shall show, if all the dimensions are increased or diminished together, the sensibility will be unchanged. If only the length of the beam is altered and the positions of the large attracting masses, so that they remain opposite to, and the same distance from, the ends of the beam, then the sensibility is inversely as the length. This mistake—for mistake it surely is—is repeated in Jamin's "Cours de Physique," tome iv. ed. iv. p. 18, where, moreover, it is emphasized by being printed in italics.

The other improvements introduced by Cornu and

Baille are the use of mercury for the attracting masses which can be drawn from one pair of vessels to the other by the observer without his coming near the apparatus, the use of a metal case connected with the earth to prevent electrical disturbances, and the electrical registration of the movements of the index on the scale, which they placed 560 centimetres from the mirror.

The great difficulty that has been met with has been the perpetual shifting of the position of rest, due partly to the imperfect elasticity or fatigue of the torsion wires, but chiefly, as Cavendish proved experimentally, to the enormous effects of air-currents set up by temperature differences in the box, which, with large apparatus, it is impossible to prevent. In every case the power of observing was in excess of the constancy of the effect actually produced. The observations of Cornu are the only ones which are comparable in accuracy with other physical measurements, and these, as far as the few figures given enable one to judge, show a very remarkable agreement between values obtained for the same quantity from time to time.

Soon after I had made quartz fibres, and found their value for producing a very small and constant torsion, I thought that it might be possible to apply them to the Cavendish apparatus with advantage. Prof. Tyndall, in a letter to a neighbour, expressed the conviction that it would be possible to make a much smaller apparatus in which the torsion should be produced by a quartz fibre. The result of an examination of the theory of the instrument shows that very small apparatus ought practically to work, but that in many particulars there is an advantage in departing from the arrangement which has always been employed, conclusions which experiment has fully confirmed.

As I have already stated, the sensibility of the apparatus is, if the period of oscillation is always the same, independent of its linear dimensions. Thus, if there are two instruments in which all the dimensions of one are n times the corresponding dimensions of the other, the moment of inertia of the beam and its appendages will be as $n^5 : 1$, and, therefore, the torsion also must be as $n^5 : 1$. The attracting masses, both fixed and movable, will be as $n^3 : 1$, and their distance apart as $n : 1$. Therefore, the attraction will be as n^6/n^2 or $n^4 : 1$, and this is acting on an arm n times as long in the large instrument as in the small; therefore the moment will be as $n^5 : 1$; that is, in the same proportion as the torsion, and so the angle of deflection is unchanged.

If, however, the length of the beam only is changed, and the attracting masses are moved until they are opposite to, and a fixed distance from, the ends of the beam, then the moment of inertia will be altered in the ratio $n^2 : 1$, while the corresponding moment will only change in the ratio of $n : 1$; and thus there is an advantage in reducing the length of the beam until one of two things happens: either it is difficult to find a sufficiently fine torsion thread that will safely carry the beam and produce the required period—and this, I believe, has up to the present time prevented the use of a beam less than $\frac{1}{2}$ metre in length—or else, when the length becomes nearly equal to the diameter of the attracting balls, they then act with such an increasing effect on the opposite suspended balls, so as to tend to deflect the beam in the opposite direction, that the balance of effect begins to fall short of that which would be due to the reduced length if the opposite ball did not interfere. Let this shortening process be continued until the line joining the centres of the masses M M makes an angle of 45° with the line $m\,m$; then, without further moving the masses M M, a still greater degree of sensibility can be obtained, provided the period remains unaltered, by reducing the length of the beam $m\,m$ to half its amount, so that the distance between the centres of M M is $2\sqrt{2}$ times the new length $m\,m$, at which point a maximum is reached.

It might be urged against this argument that a difficulty would arise in finding a torsion fibre that would give to a very short beam, loaded with balls that it will safely carry, a period as great as five or ten minutes, and until quartz fibres existed there would have been a difficulty in using a beam much less than a foot long, but it is now possible to hang one only half an inch long and weighing from twenty to thirty grains by a fibre not more than a foot in length, so as to have a period of five minutes. If the moment of inertia of the heaviest beam of a certain length that a fibre will safely carry is so small that the period is too rapid, then the defect can be remedied by reducing the weight, for then a finer fibre can be used, and since the torsion varies approximately as the square of the strength (not exactly, because fine fibres carry heavier weights in proportion), the torsion will be reduced in a higher ratio, and so by making the suspended parts light enough, any slowness that may be required may be provided.

Practically, it is not convenient to use fibres much less than one ten-thousandth of an inch in diameter, and these have a torsion 10,000 times less than that of ordinary spun glass. A fibre one five-thousandth of an inch in diameter will carry a little over thirty grains.

Since with such small apparatus as I am now using it is easy to provide attracting masses which are very large in proportion to the length of the beam, while with large apparatus comparatively small masses must be made use of owing to the impossibility of dealing with balls of lead of great size, it is clear that much greater deflections can be produced with small than with large apparatus. For instance, to get the same effect in the same time from an instrument with a 6-foot beam that I get from one in which the beam is five-eighths of an inch long, and the attracting balls are 2 inches in diameter, it would be necessary to provide and deal with a pair of balls each 25 feet in diameter, and weighing 730 tons instead of about $1\frac{3}{4}$ pound apiece. There is the further advantage in small apparatus that if for any reason the greatest possible effect is desired, attracting balls of gold would not be entirely unattainable, while such small masses as two piles of sovereigns could be used where qualitative effects only were to be shown. Owing to its strongly magnetic qualities, platinum is unsuited for experiments of this kind.

By far the greatest advantage that is met with in small apparatus is the perfect uniformity of temperature which is easily obtained, whereas, with apparatus of large size, this alone makes really accurate work next to impossible. The construction to which this inquiry has led me, and which will be described later, is especially suitable for maintaining a uniform temperature in that part of the instrument in which the beam and mirror are suspended.

With such small beams as I am now using it is much more convenient to replace the long thin box generally employed to protect the beam from disturbance by a vertical tube of circular section, in which the beam with its mirror can revolve freely. This has the further advantage that, if the beam is hung centrally, the attraction of the tube produces no effect, and the troublesome and approximate calculations which have been necessary to find the effect of the box are no longer required. The attracting weights, which must be outside the tube, must be made to take alternately positions on the two sides of the beam, so as to deflect it first in one direction and then in the other. For this purpose they are most conveniently fastened to the inside of a larger metal tube, which can be made to revolve on an axis coincident with the axis of the smaller tube. There are obviously two planes, one containing and one at right angles to the beam, in which the centres of the attracting balls will lie when they produce no deflection. At some intermediate position the deflection will be a maximum. Now, it is a matter of some importance to choose this maximum

position for the attracting masses, because, in showing the experiment to an audience, the largest effect should be obtained that the instrument is capable of producing; while in exact measures of the constant of gravitation this position has the further advantage that the only measurement which there is any difficulty in making, viz. the angle between the line joining the large masses and the line joining the small, which may be called the azimuth of the instrument, becomes of little consequence under these circumstances. In the ordinary arrangement the slightest uncertainty in this angle will produce a relatively large uncertainty in the result. I have already stated that if an angle of 45° is chosen, the distance between the centres of the large balls should be $2\sqrt{2}$ times the length of the beam, and the converse of course is true. As it would not be possible at this distance to employ attracting balls with a diameter much more than one and a half times the length of the beam, and as balls much larger than this are just as easily made and used, I have found by calculation what are the best positions when the centres of the attracting balls are any distance apart.

If the effect on the nearer ball only is considered, then it is easy to find the best position for any distance of the attracting mass from the axis of motion. Let P (Fig. 2) be the centre of the attracting ball, N that of the nearer

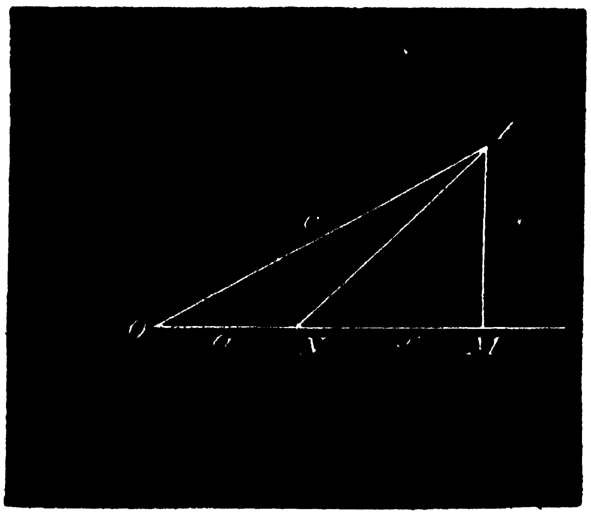

FIG. 2.

attracted ball, O the axis of motion, c and a the distances of P and N from O, and x the distance from N of the foot of the perpendicular from P on ON produced. Then the moment of N about O will be greatest when

$$x^2 + \frac{3a^2 + c^2}{a} x = 2(c^2 - a^2),$$

or what comes to the same thing when

$$\cos^2\theta + \frac{c^2 + a^2}{ca}\cos\theta = 3.$$

Now, as the size of the attracting masses M M is increased, or, as is then necessarily the case, as the distance of their centres from the axis increases, their relative action on the small masses *m m* at the opposite ends of the beam increases, and so but a small fraction of the advantage is obtained, which the large balls would give if they acted only upon the small balls on their own side. For instance, if the distance between the centres of M M is five times the length of the beam, the moment due to the attraction on the opposite small balls is nearly half as great as that on the near balls, so that the actual sensibility is only a little more than half that which would be obtained if the cross action could be prevented.

I have practically overcome this difficulty by arranging the two sides of the apparatus at different levels. Each large mass is at or near the same level as the neighbouring small one, but one pair is removed from the level of the other by about the diameter of the large masses which in the apparatus figured below is nearly five times as great as the distance *in plan* between the two small masses.

In order to realize more fully the effect of a variety of arrangements, I have, for my own satisfaction, calculated the values of the deflecting forces in an instrument in which the distance between the centres of the attracting balls is five times the length of the beam, for every azimuth and for differences of levels of 0, 1, 2, 3, 4, and 5 times the length of the beam.

The result of the calculation is illustrated by a series of curves in the original paper. The main result, however, is this.

In the particular case which I have chosen for the instrument, *i.e.* where the distance between the centres of M M and the axis, and the difference of level between the two sides are both five times the length of the beam, as seen in plan, and where the diameter of the large masses is 6·4 times the length of the beam, the angle of deflection becomes 18·7 times as great as the corresponding angle in the apparatus of Cavendish, provided that the large masses are made of material of the same density in the two cases and the periods of oscillation are the same.

Having now found that with apparatus no bigger than an ordinary galvanometer it should be possible to make an instrument far more sensitive than the large apparatus in use heretofore, it is necessary to show that such a piece of apparatus will practically work, and that it is not liable to be disturbed by the causes which in large apparatus have been found to give so much trouble.

I have made two instruments, of which I shall only describe the second, as that is better than the first, both in design and in its behaviour.

The construction of this is made clear by Fig. 3. To a brass base provided with levelling screws is fixed the vertical brass tube *t*, which forms the chamber in which the small masses *a b* are suspended by a quartz fibre from a pin at the upper end. These little masses are cylinders[1] of pure lead 11·3 millimetres long and 3 millimetres in diameter, and the vertical distance between their centres is 50·8 millimetres. They are held by light brass arms to a very light taper tube of glass, so that their axes are 6·5 millimetres from the axis of motion. The mirror *m*, which is 12·7 millimetres in diameter, plane, and of unusual accuracy, is fastened to the upper end of the glass tube by the smallest quantity of shellac varnish. Both the mirror and the plate-glass window which covers an opening in the tube were examined, and afterwards fixed with the refracting edge of each horizontal, so that the slight but very evident want of parallelism between their faces should not interfere with the definition of the divisions of the scale. The large masses M M are two cylinders[1] of lead 50·8 millimetres in diameter, and of the same length. They are fastened by screws to the inside of a brass tube, the outline of which is dotted in the figure, which rests on the turned shoulder of the base, so that it may be twisted without shake through any angle. Stops (not shown in the figure) are screwed to the base, so that the actual angle turned through shall be that which produces the maximum deflection. A brass lid made in two halves covers in the outer tube, and serves to maintain a very perfect uniformity of temperature in the inner tube. Neither the masses M M, nor the lid, touch the inner tube. The period of oscillation is 160 seconds.

With this apparatus placed in an ordinary room with

[1] Cylinders were employed instead of spheres, because they are more easily made and held, and because spheres have no advantage except when absolute calculations have to be made. Also the vertical distance *a b* was for convenience made only about four times the length *a b* in plan.

draughts of air of different temperatures and with a lamp and scale such as are used with a galvanometer, the effect of the attraction can easily be shown to a few, or, with a lime-light, to an audience. To obtain this result with apparatus of the ordinary construction and usual size is next to impossible, on account chiefly of the great disturbing effect of air currents set up by difference of temperature in the case. The extreme portability of the new instrument is a further advantage, as is evident when the enormous weight and size of the attracting masses in the ordinary apparatus are considered.

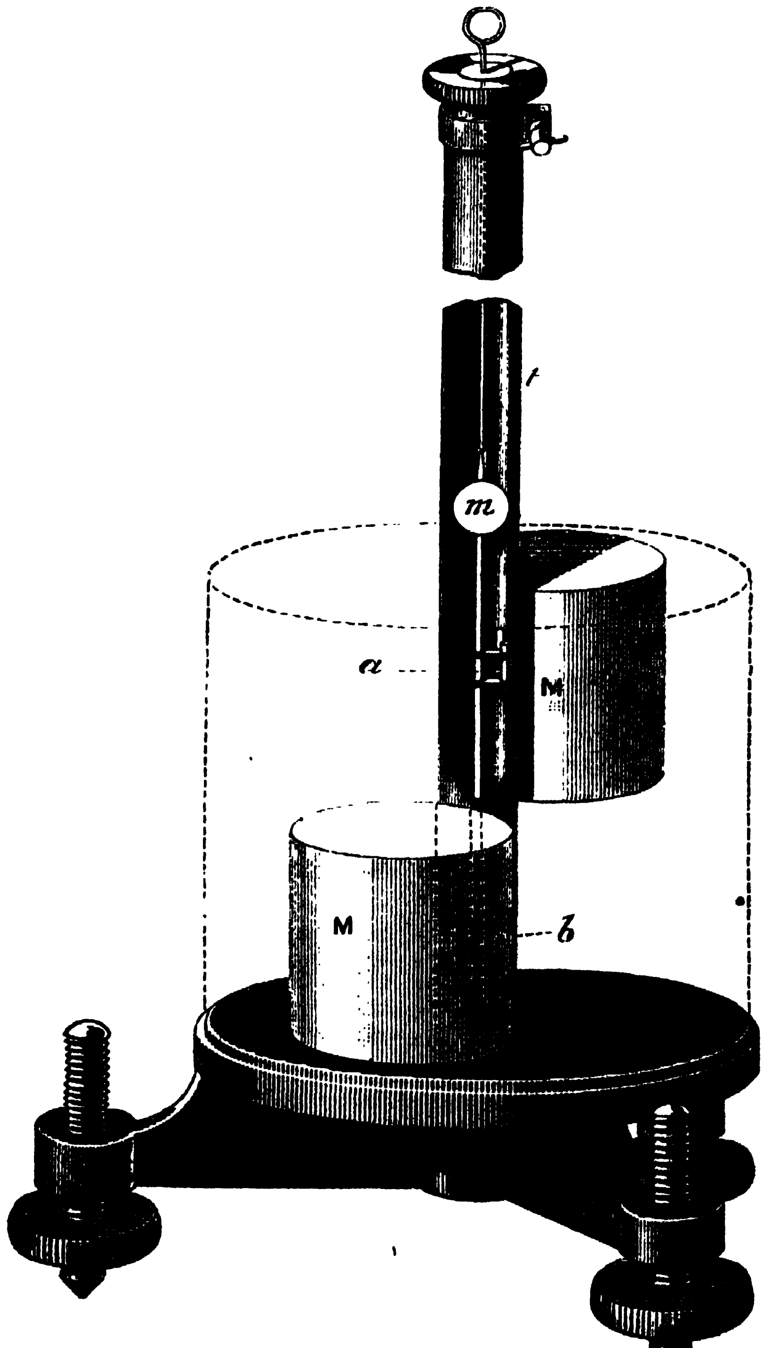

FIG. 3.

However, this result is only one of the objects of the present inquiry. The other object which I had in view was to find whether the small apparatus, besides being more sensitive than that hitherto employed, would also be more free from disturbances and so give more consistent results. With this object I have placed the apparatus in a long narrow vault under the private road between the South Kensington Museum and the Science Schools. This is not a good place for experiments of this kind, for when a cab passes overhead the trembling is so great that loose things visibly move; however, it is the only place at my disposal that is in any degree suitable. A large drain-pipe filled with gravel and cement and covered by a slab of stone forms a fairly good table. The scale is made by etching millimetre divisions on a strip of clear plate glass 80 centimetres long. This is secured at the other end of the vault at a distance of 1053·8 centimetres from the mirror of the instrument. A telescope 132 centimetres long with an object-glass 5·08 centimetres in diameter, rests on V's clamped to the wall, with its object-glass 360 centimetres from the mirror. Thus any disturbance that the observer might produce if nearer is avoided, and at the same time the field of view comprises 100 divisions. While the observer is sitting at the telescope he can, by pulling a string, move an albo-carbon light, mounted on a carriage, so as to illuminate any part of the scale that may happen to be in the field of the telescope. The white and steady flame forms a brilliant background on which the divisions appear in black. The accuracy of the mirror is such that the millimetre divisions are clearly defined, and the position of the cross-wire (a quartz fibre) can be read accurately to one-tenth of a division. This corresponds to a movement of the mirror of almost exactly one second of arc.

The mode of observation is as follows: When all is quiet with the large masses in one extreme position, the position of rest is observed and a mark placed on the scale. The masses are moved to one side for a time and then replaced, which sets up an oscillation. The reading of every elongation and the time of every transit of the mark are observed until the amplitude is reduced to 3 or 4 centimetres. The masses are then moved to the other extreme position and the elongations and transits observed again, and this is repeated as often as necessary.

On the evening of Saturday, May 18, six sets of readings were taken, but during the observations there was an almost continuous tramp of art students above, producing a perceptible tremor, besides which two vehicles passed, and coals were twice shovelled in the coal cellar, which is separated from the vault in which the observations were made by only a 4½-inch brick wall. The result of all this was a nearly perpetual tremor, which produced a rapid oscillation of the scale on the cross-wire, extending over a little more than 1 millimetre. This increased the difficulty of taking the readings, but to what extent it introduced error I shall not be able to tell until I can make observations in a proper place.

In spite of these disturbances, the agreement between the deflections deduced from the several sets of observations, and between the periods, is far greater than I had hoped to obtain, even under the most favourable conditions. In order to show how well the instrument behaved, I have copied from my note-book the whole series of figures of one set, which sufficiently explain themselves.

Elongation.	Amplitude.	Decrement.	True Position of Rest.	Time of Transit of 36·09.	Correction for Transit of True Position of Rest.	True Half Period.
				h. m. s.		
15·05	38·15	0·805	36·18	9 8 25·0	+ 0·08	80·2
53·20	30·72	0·808	36·20	9 45·5	− 0·18	80·2
22·48	24·80	0·807	36·21	11 5·3	+ 0·24	80·0
47·28	20·00	0·807	36·20	12 25·8	− 0·28	79·9
27·28	16·12	0·805	36·22	13 45·0	+ 0·41	80·1
43·40	12·98	0·806	36·21	15 6·0	− 0·47	80·1
30·42	10·46	0·802	36·22	16 25·0	+ 0·63	79·5
40·88	8·38	0·808	36·24	17 46·0	− 0·91	80·5
32·50	6·77	0·808	36·24	19 4·5	+ 1·13	79·8
39·27	5·47	0·814	36·26	20 27·0	− 1·58	80·5
33·80	4·45		36·26	21 44·0	+ 1·94	
38·25						
		0·8066				80·08

It will be noticed that the true position of rest is slightly rising in value, and this rise was found to continue at the rate of 0·36 centimetre an hour during the whole course of the experiment, and to be the same when the large masses were in the positive or negative position. The motion was perfectly uniform, and in no way interfered with the accuracy of the experiments. It was due, I believe, to the shellac fastening of the fibre, for I find that immediately after a fibre has been attached, this movement is very noticeable, but after a few days it almost entirely ceases; it is, moreover, chiefly eviden when the fibre is loaded very heavily. At the time tha the experiment was made the instrument had only been set up a few hours.

The mean decrement of three positive sets was 0·8011 and of three negative sets, 0·8035. The observed mean period of three positive sets was 79·98, and of three negative sets, 80·03 seconds, from both of which 0·20 must be deducted as the time correction for damping.

The deflections, in centimetres, obtained from the six sets of observations taken in groups of three, so as to take into account the effect of the slow change of the position of rest, were as follows:—

From sets 1, 2, and 3	...	17·66 ± 0·01
,, 2, 3, and 4	...	17·65 ± 0·02
,, 3, 4, and 5	...	17·65 ± 0·02
,, 4, 5, and 6	...	17·65 ± 0·02

An examination of these figures shows that the deflection is known with an accuracy of about one part in two thousand, while the period is known to the 4000th part of the whole. As a matter of fact, the discrepancies are not more than may be due to an uncertainty in some of the observations of ½ millimetre or less, a quantity which, under the circumstances, is hardly to be avoided.

The result of these experiments is complete and satisfactory. As a lecture experiment, the attraction between small masses can be easily and certainly shown, even though the resolved force causing motion is, as in the present instance, no more than the 1/200,000 of a dyne (less than 1/10,000,000 of the weight of a grain), and this is possible with the comparatively short half period of 80 seconds. Had it been necessary to make use of such half periods as three to fifteen minutes, which have been employed hitherto, then, even though a considerable deflection were produced, this could hardly be considered a lecture experiment. So perfectly does the instrument behave, that there can be no difficulty in making a fairly accurate measure of the attraction between a pair of No. 5, or, I believe, even of dust shot.

The very remarkable agreement between successive deflections and periods shows that an absolute measure made with apparatus designed for the purpose, but on the lines laid down above, is likely to lead to results of far greater accuracy than any that have been obtained. For instance, in the original experiment of Cavendish there seems to have been an irregularity in the position of rest of one-tenth of the deflection obtained, while the period showed discrepancies of five to fifteen seconds in seven minutes. The experiments of Baily, made in the most elaborate manner, were more consistent, but Cornu was the first to obtain from the Cavendish apparatus results having a precision in any way comparable to that of other physical measurements. The three papers, published by him in the *Comptes rendus* of 1878, referred to above, contain a very complete solution of some of the problems to which the investigation has given rise. The agreement between the successive values, decrement, and period is much the same as I have obtained, nevertheless the means of the summer and of the winter observations differ by about 1 per cent.

I have not referred to the various methods of determining the constant of gravitation in which a balance, whether with the usual horizontal beam, or with a vertical beam on the metronome principle, is employed. They are essentially the same as the Cavendish method, except that there is introduced the friction of the knife-edges and the unknown disturbances due to particles of dust at these points, and to buoyancy, without, in my opinion, any compensating advantage. However, it would appear that if the experiment is to be made with a balance, the considerations which I have advanced in this paper would point to the advantage of making the apparatus small, so that attracting masses of greater proportionate size may be employed, and the disturbance due to convection reduced.

It is my intention, if I can obtain a proper place in which to make the observations, to prepare an apparatus specially suitable for absolute determinations. The scale will have to be increased, so that the dimensions may be determined to a ten-thousandth part at least. Both pairs of masses should, I think, be suspended by fibres or by wires, so that the distance of their centres from the axis may be accurately measured, and so that, in the case of the little masses, the moment of inertia of the beam, mirror, &c., may be found by alternately measuring the period with and without the masses attached. The unbalanced attractions between the beam, &c., and the large masses, and between the little masses and anything unsymmetrical about the support of the large masses, will probably be more accurately determined experimentally by observing the deflections when the large and the small masses are in turn removed, than by calculation.

If anything is to be gained by swinging the small masses in a good Sprengel vacuum, the difficulty will not be so great with apparatus made on the scale I have in view, *i.e.* with a beam about 5 centimetres long, as it would with large apparatus. With a view to reduce the considerable decrement, I did try to maintain such a vacuum in the first instrument, in which a beam 1·2 centimetre long was suspended by a fibre so fine as to give a complete period of five minutes, but though the pump would click violently for a day perhaps, leakage always took place before long, and so no satisfactory results were obtained.

With an apparatus such as I have described, but arranged to have a complete period of six minutes, it will be possible to read the scale with an accuracy of 1/10,000 of the deflection, and to determine the time of vibration with an accuracy about twice as great.

I hope early next year, in spite of the difficulty of finding a suitable place to observe in, to prepare apparatus for absolute determinations, and I shall be glad to receive any suggestions which those interested may be good enough to offer.

C. V. BOYS.

WILLIAM RAMSAY McNAB.

WILLIAM RAMSAY McNAB, M.D., whose sudden death from heart-disease we have already recorded, was born in Edinburgh in November 1844. He was educated at the Edinburgh Academy, and afterwards in the University of that city, obtaining the degree of Doctor of Medicine when twenty-two years of age.

His grandfather and father, in succession, held office as Curators of the Edinburgh Botanic Garden; and the late Dr. McNab early manifested an inherited capacity for botanical work; for, while still an undergraduate, he was appointed assistant to Prof. Balfour, who then held the Edinburgh botanical chair. He also entered the University of Berlin as a student—in botany under Profs. Braun and Koch, and in pathological anatomy and histology under Prof. Virchow. Three years of his later life were spent in medical practice; but his love of botany was his dominant feeling, and in 1870 he embarked upon a purely biological career, having been then appointed to the Professorship of Natural History

in the Royal Agricultural College, Cirencester. Two years later he succeeded to the Chair of Botany in the Royal College of Science, Dublin, and this post he held until his death. During his student life he paid considerable attention to the practical study of geology; and for many years he collected Coleoptera, of which he possessed a very fine collection, now in the Dublin Museum of Science and Art.

During the nineteen years exclusively devoted to natural science, Prof. McNab published a considerable number of technical papers; most of these were short, but some forty or fifty of them are fit to rank as original communications. The work by which he is best known was that upon the movements of water in plants. Following a suggestion of Prof. A. H. Church, that lithium might prove useful in his researches, he instituted experiments which proved the value of this method, and paved the way for later investigators. McNab's chief claim to distinction lay, however, not in the direction of pure research, but in the fact of his having been the first to introduce to British students the methods of Sachs, now universally adopted. He inaugurated the modern methods of teaching botany at Cirencester, in the year 1871, and at Dublin two years later; and he fully admitted his indebtedness to the first edition of Sachs's celebrated "Lehrbuch der Botanik." Dr. McNab was, at the time of his death, an examiner in botany to the Victoria University, Manchester. The appointment of Scientific Superintendent of the Royal Botanic Gardens, Glasnevin, Dublin, was created for him in 1880, and in connection with this office he issued, five years later, an enlarged and considerably revised Guide-book. He was joint author, with Prof. Alex. Macalister, of a "Guide-book to the County of Dublin," prepared on the occasion of the visit of the British Association to that city. In 1878 he published, in Longmans' "London Science Series," two botanical class-books, entitled "Outlines of Morphology and Physiology," and "Outlines of Classification"; and he leaves behind him the first few chapters, and a large amount of manuscript in a nearly completed condition, of a contemplated "Text-book of Botany," which he was to have written for Messrs. C. Griffin and Co. In 1888 he was appointed Swiney Lecturer to the British Museum of Natural History, and in that capacity he has lectured for two sessions. His discourses, which were upon "The Fossil Plants of the Palæozoic Epoch" and "Ferns and Gymnosperms of the Palæozoic and Mesozoic Epochs, and dawn of the Angiospermous Flora" respectively, were attended with much success. He has left behind him carefully written manuscript lectures, which it is sincerely hoped may be published as a memorial volume. At the time of his decease he was actively engaged upon his intended third course, in which he would have dealt with the Cainozoic flora. He was an excellent teacher, possessed of a natural aptitude for the work; and his laboratory instruction was characterized by thoroughness and precision. As a lecturer he was fluent and entertaining; and, in his several capacities, he endeared himself to those with whom he came in contact. Friends, colleagues, and students, alike mourn his loss.

NOTES.

THE death of Prof. Lorenzo Respighi, Director of the Osservatorio Campidoglio, Rome, which we deeply regret to announce, is a great loss to science. He died on December 10.

IN a recent number we gave some account of a meeting held in Manchester on November 25 for the purpose of preparing the way for the erection of a memorial of James Prescott Joule in that city. It was resolved that the memorial should be in the form of a white marble statue, and a committee was appointed to carry out this resolution. At the first meeting of the committee, on November 29, an executive committee was appointed, and the following motion was adopted:—"That the movement be directed to secure, not only a marble statue of the late Dr. James Prescott Joule as a companion to that of the late Dr. Dalton by Sir Francis Chantrey, but also a replica in bronze to occupy some public place in the city, and that the executive committee be instructed to take all needful steps for that purpose." Many subscriptions have been already promised.

AN attempt is being made to secure the erection of an international monument to James Watt at Greenock, his birthplace. It is proposed that the memorial shall be "a large and thoroughly equipped technical school."

A NEW fortnightly scientific periodical is about to be published in Paris. It will be entitled *Revue Générale des Sciences Pures et Appliquées*, and will deal with the mathematical, physical, and natural sciences, and with their applica-tions in geodesy, navigation, engineering, manufactures, agriculture, hygiene, medicine, and surgery. According to the preliminary statement, the new periodical will take as its model the method of exposition adopted in NATURE. The editor is M. Louis Olivier, and the list of contributors includes many of the most eminent French men of science. The first number will appear on January 15, 1890.

THE second Report of the Committee appointed by the British Association to inquire into, and report upon, the present methods of teaching chemistry, which was presented at the Newcastle meeting, and to which we called attention in these columns a short time ago, has now been put on sale by the Council. It may be obtained from the office of the Association, 22 Albemarle Street, W.

ON Tuesday evening, after the distribution of the prizes and certificates to the students of the City and Guilds of London Institute, at Goldsmiths' Hall, Sir Henry Roscoe congratulated the students of the various schools upon the reports he had heard. He observed that the City Guilds were now engaged separately and collectively in nobly carrying out the work for which they were, to a certain extent, originally founded. The Technical Instruction Bill which was passed in the last session of Parliament had materially changed the whole aspect of affairs, and sooner or later a complete scheme for technical education would have to be framed. The beginning of such a scheme had been made by the efforts of the City of London Institution, which, with its many branches, was a nucleus of such a system, the importance of which would only be recognized when the history of that important movement came to be written. It was a satisfactory thing to hear that employers of skilled labour were beginning to find out that the men who had been trained at such Colleges as these were of greater value than those who had not received such training. It was not only necessary to educate the craftsman; the employer needed it equally, if not more. He thought that the Council of the Institute had fully recognized that fact at their Central Institution, but a demand for high-class education had yet to be created.

THE *British Medical Journal* says that owing to the somewhat late period in the year at which the invitation to hold the annual meeting of the British Medical Association in Birmingham was received and accepted, the arrangements are not yet so complete as in former years; but a large general committee and all the necessary sub-committees have been formed, and the use of the requisite public buildings has been obtained.

ON March 1, 1890, a new marine laboratory will be opened at Saint-Wast-la-Hougue.

WE are glad to know that there will soon be well-equipped physical and chemical laboratories at Bedford College, London. Mr. Tate, who has already given £1000 towards the new College buildings, which are on the eve of completion, has

offered a second £1000 towards the fitting up and equipment of the laboratories, contingent on the friends of the College contributing an equal amount. We purpose shortly giving an account and plans of these laboratories.

MORE than a quarter of a century has passed since it was decided that the *Entomologist's Monthly Magazine* should be started. The editors have now resolved to issue a new series, each volume of which will begin in January and end in December. There will be no radical change in the constitution of the magazine, but the number of pages and illustrations will often be increased.

THE result of the poll for a free library at Whitechapel, declared last Saturday night, is interesting and significant. On a register of 6000, there were 3553 affirmative votes and only 935 dissentients. This is the more noteworthy, because about eleven years ago a like proposal was rejected by a majority of about two to one.

THE following science lectures will be given at the Royal Victoria Hall during January: January 7, "A Visit to the Chief Cities of Italy," by Rev. W. W. Edwards; January 14, "The Bottom of the Sea," by Dr. P. H. Carpenter; January 21, "To Vancouver's Island and back," by Mr. W. L. Carpenter; January 28, "Musical Sounds and how we hear them," by Dr. F. W. Mott.

A SECOND edition of Sir William Aitken's "Animal Alkaloids" (H. K. Lewis) has been published. The work has been carefully revised, and the author's aim has been to bring the book up to the present state of knowledge regarding the important subject to which it relates.

THE first part of a monograph of Oriental *Cicadidæ*, by W. L. Distant, has been published by order of the Trustees of the Indian Museum, Calcutta. It is printed in clear type, and includes two fine plates. The monograph, when completed, will evidently be of much scientific value.

M. VAYSSIÈRE has now completed the publication of his "Atlas d'Anatomie Comparée des Invertébrés." It comprises sixty plates, with corresponding letterpress, and is much appreciated by French zoologists.

THE Proceedings and Transactions of the International Agricultural Congress held in Paris last summer have just been issued.

A REUTER'S telegram from Madrid says that a shock of earthquake was felt at Granada on the evening of December 16. There was great alarm for the moment, and the people rushed in panic out of the theatre, where a performance was going on at the time. Apparently no damage was done.

THE Pilot Chart of the North Atlantic Ocean for December states that stormy weather has been prevalent during the month of November. Two notable cyclones have occurred; the first moved eastward from Chesapeake Bay on the night of the 9th. On the 11th it was central in about latitude 41° N., longitude 57° W.; and from this position it moved nearly due north-east, and rapidly increased in energy. The other cyclone moved eastward from the New Jersey coast on the 13th, and was central on the 14th in latitude 42° 40′ N., longitude 63° 20′ W. This storm attained great violence during the 14th and 15th. After the 16th, gales of varying force occurred along the coast north of Florida. There was very little fog during the month; a dense bank was reported on the 17th on the north coast of Cuba. A number of icebergs are still reported in the vicinity of Belle Isle, and several smaller bergs have been seen over the Newfoundland Banks.

AT the meeting of the French Meteorological Society on November 5, M. Teisserenc de Bort gave an account of his researches on barometric gradients. He distinguished two kinds of gradients, one due to the differences of temperature, and another due to the earth's rotation, and pointed out that these two gradients are always superposed, and that their distinction was a matter of importance, for if the first case predominates (a gradient due to difference of temperature), the wind force may increase and the depression become deeper, while in the second case the depression tends to disappear. He thought it was not impossible to make this distinction, for if we know the force of the wind we might calculate the moment of inertia and the corresponding gradient. He also presented a work on the distribution of atmospheric pressure over the surface of the globe. He showed that the distribution of pressure over different meridians varies upwards of an inch on the same parallel according to the season. With the view of finding out the arrangement of the isobars in higher regions of the atmosphere, the author has calculated the pressures by formulæ at various heights, from the pressure and temperature observed at the earth's surface, and compared their accuracy by the readings at some mountain stations, and he has found that most of the irregularities in the distribution of the isobars tend to disappear as we reach the higher regions of the air, and to be replaced by inflexions in the opposite sense. A summary of this paper will be found in the *Comptes rendus* of the French Academy for December 2.

AT a meeting of the Linnean Society of New South Wales on October 30, Mr. A. Sidney Olliff called attention to the extraordinary abundance of a large Noctuid moth—apparently *Agrotis spina*, Gu. (*A. vastator*, Sc.)—during the early part of October in various parts of the country, especially in the vicinity of Sydney, where it appeared in such vast numbers as to cause great consternation amongst those who were not aware that its food in the larval state is confined to low-growing herbage, and that at no stage of its existence does it eat cloth, furs, or feathers. A similar visitation of these moths occurred in October 1867. Mr. Olliff said that *Agrotis spina* was found in great numbers on the summit of Mount Kosciusko and other high points in the Australian Alps, and added that he was of opinion, after extended inquiry, that this species, and no other, was the true Bugong moth, which formerly formed an important article of food amongst the blacks of the Upper Tumut district.

MR. THOMAS CORNISH, Penzance, recently recorded in *The Zoologist* the occurrence of the "Old English" or "Black" Rat, captured at a place about five miles north-east of Penzance. In the current number of the same periodical he says that immediately after that capture a perfectly trustworthy observer saw near Camborne, at a place ten miles south-east from where the first specimen was obtained, a Black Rat, which was certainly not the ordinary Hanoverian Rat; and at a later time Mr. Cornish saw and handled another specimen, captured in Paul Parish, about three miles south-west of Penzance. "These facts," says Mr. Cornish, "apparently point to an incursion of this animal, which is gregarious certainly, and probably a vagrant in herds, but not a migrant."

MR. J. R. DOBBINS, San Gabriel, California, contributes to the new number of *Insect Life* (vol. ii. No. 4) a note on the spread of the Australian ladybird. The note is dated July 2, 1889. At that time the Vedolia had multiplied in numbers, and had spread so rapidly that every one of Mr. Dobbins's 3200 orchard trees was literally swarming with them. All his ornamental trees, shrubs, and vines which had been infested with white scale were practically cleansed by this wonderful parasite. "About one month since," says Mr. Dobbins, "I made a public statement that my orchard would be free from 'Icerya by November 1,' but the work has gone on with such amazing speed and thoroughness, that I am to-day confident that the pest will have been exterminated from my trees by the middle of August. People are coming here daily, and by placing infested branches upon the ground beneath my trees for two hours, can secure

colonies of thousands of the Vedolia, which are there in countless numbers sucking food. Over 50,000 have been taken away to other orchards during the present week, and there are millions still remaining, and I have distributed a total of 63,000 since June 1. I have a list of 130 names of persons who have taken the colonies, and as they have been placed in orchards extending from South Pasadena to Azusa, over a belt of country ten miles long and six or seven in width, I feel positive, from my own experience, that the entire valley wiil be practically free from Icerya before the advent of the new year."

COCOA-NUT butter is now being made at Mannheim, and, according to the American Consul there, the demand for it is steadily increasing. The method of manufacture was discovered by Dr. Schlunk, a practical chemist at Ludwigshafen. Liebig and Fresenius knew the value of cocoa-nut oil or fat, but did not succeed in producing it as a substitute for butter. The new butter is of a clear whitish colour, melts at from 26° to 28° C., and contains 0·0008 per cent. water, 0·006 per cent. mineral stuffs, and 99·9932 per cent. fat. At present it is chiefly used in hospitals and other State institutions, but it is also rapidly finding its way into houses or homes where people are too poor to buy butter. The working classes are taking to it instead of the oleomargarines against which so much has been said during the last two or three years.

A POINT of great importance for the progress of Western science in the Chinese Empire is whether it should be taught in the Chinese or in a foreign language. The subject has been frequently discussed, and quite recently the opinions of a large number of men most prominently engaged in the education of Chinese were collected and published in a Shanghai magazine, the *Chinese Recorder*. The editor says that nine-tenths of these authorities are of opinion that the Chinese language is sufficient for all purposes in teaching Western science. One gentleman states that Chinese students can only be taught science in their own language, and that the long time necessary for them to acquire English for this purpose is wasted; another says that "science must be planted in the Chinese language in order to its permanent growth and development"; a third sees no reason why the vernacular should not be enough to allow the Chinese student to attain the very highest proficiency in Western science, although he admits that there is at present a want of teachers and text-books. Prof. Oliver, of the Imperial University at Pekin, says he has never found English necessary, but has always taught in Chinese. Prof. Russell, of the same institution, finds Chinese sufficient for popular astronomy. On the other hand, Mr. Tenney says that it can only be for the most popular views of science that the vernacular is sufficient. "It is impossible," he says, "for scholars who are ignorant of any European language to attain any such excellence in modern sciences as to enable them to bear comparison with the finished mathematical and scientific scholars of Europe and America." Thus, he continues, as a medium of thought, any Western language is incomparably superior to Chinese in precision and clearness; the student acquainted with a foreign language has a vast field of collateral thought open to him which does not and never will exist in Chinese, and he can keep abreast of the times, which the Chinese student who must depend on translations cannot do. The relation of the Chinese student "to the world of thought is analogous to that of a blind and deaf person in the West, whose only sources of knowledge are the few and slowly increasing volumes of raised type letters which make up the libraries of the blind." As has been said, however, the weight of opinion is against Mr. Tenney.

IN a recent number of *Humboldt*, Herr Fischer-Sigwart describes the ways of a snake, *Tropidonotus tessellatus*, which he kept in his terrarium in Zurich. It was fond of basking in the sun on the top of a laurel, from which it climbed easily to a high cherry-tree fixed against a wall, its night quarters. Sometimes, after lying still for hours, it would hasten down into a snall pond (about 4 square yards surface) containing gold-fish, and hide itself for a long time, quite under water, behind some stone, or plants, the tongue constantly playing. When a fish came near, the snake would make a dart at its belly. Often missing, it would lose patience, and swim after the fishes, driving them into some corner, where it at length seized one in the middle of the belly, and carried it to land, much as a dog would a piece of wood. Curiously, the fish, after being seized, became quite still and stiff, as if dead. If one then liberated it, the skin of the belly was seen to be quite uninjured, and the fish readily swam away in the water. The author thinks the snake has a hypnotic influence on its prey (and he had observed similar effects with a ringed snake). It would otherwise be very difficult for the snake to retain hold of a wriggling fish. The snake usually carried off the fish some distance to a safe corner, to devour it in peace.

A SPLENDID find of minerals containing the rare metals of the yttrium and thorium groups has been made in Llano County, Texas (*Amer. Journ. of Science*, December 1889). The whole district for many miles round consists almost entirely of Archæan rocks, granite being met with everywhere, and forming the common wayside rock. Throughout the granite are dispersed veins of quartz, and it is in these veins, and especially the swellings of the veins, that large masses of rare minerals have been found. The largest of these deposits consist of gadolinite and fergusonite, and of two entirely new minerals, to which the names yttrialite and thoro-gummite have been given. The first discovery of gadolinite in Texas was made in 1886, when a pocket of huge crystals and masses aggregating to about 500 kilogrammes was unearthed. Since that time a more complete prospection of the district has revealed the existence of still larger quantities. The gadolinite is generally found in small lumps weighing about half a pound, but frequently also in much heavier masses, and sometimes in immense crystals. One double crystal was found weighing 42 pounds, and a still larger single crystal weighed no less than 60 pounds. And these immense crystals actually contain over 50 per cent. of oxides of the yttrium metals, as do also the massive varieties. The crust of the gadolinite crystals, which appear to be of monoclinic habit, was generally altered into a brownish-red hydrate of waxy lustre; but occasionally, as in case of two particular specimens, the crystals were found in a state of rare beauty and perfection. The new mineral yttrialite, a thorium-yttrium silicate, was discovered associated with and often upon the gadolinite. It was generally altered at the surface to an orange-yellow hydrate of quite different structure to that of the hydrate of gadolinite. One mass of this incrustation was found to weigh over 10 pounds. It contains 46 per cent. of oxides of the yttrium metals. Fergusonite, hitherto an exceedingly rare mineral, occurs in large quantities in the Llano County district, generally in the form of broken interlacing prisms several inches long. Two varieties of it have been identified—one a monohydrated and the other a trihydrated variety. The monohydrated kind forms tetragonal prisms with acute pyramidal terminations, of dull gray exterior, but possessing a brilliant bronze-like fracture. It contains 42 per cent. of yttrium earths and 46 per cent. of columbic acid, Cb_2O_5. The trihydrated variety is similar, but of a dark brown colour. Associated with the fergusonite is the new mineral thoro-gummite, a hydrated uranium thoro-silicate. This mineral is frequently found in well-developed crystals resembling, and having angles very nearly the same as, those of zircon. It contains 22 per cent. of UO_3, 41 per cent. of ThO_2, and 6 per cent. of yttrium earths. Its probable essential composition is $UO_3 . 3ThO_2 . 3SiO_2 . 6H_2O$. Besides these four minerals of special interest to chemists, many more—such as,

cyrtolite, molybdite, allanite, tengerite, and a new hydrated thorium-yttrium-lead uranate, termed nivenite—have been found. Altogether, this is the richest find of rare earths which has been heard of for some time, and will probably exert a fresh impetus upon the attempts to set our knowledge of the rare-earth elements upon a surer foundation.

THE additions to the Zoological Society's Gardens during the past week include a Ring-tailed Coati (*Nasua rufa* ♂) from South America, presented by Mrs. Petre; a Common Squirrel (*Sciurus vulgaris*), British, presented by Mrs. S. Stutterd; a Short-eared Owl (*Asio brachyotus*) from Hampshire, presented by Mr. E. Hart, F.Z.S.; two Owen's Apteryx (*Apteryx oweni*) from New Zealand, presented by Captain C. A. Findlay, R.N.R., R.M.S.S. *Ruapehu*; four Common Vipers (*Vipera berus*) from Hampshire, presented by Mr. W. H. B. Pain; a Marsh Ichneumon (*Herpestes galera*) from South Africa, purchased; a —— Troupial (*Xanthosomus frontalis*) from Brazil, received in exchange.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m., December 19 = 3h. 54m. 45s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G. C. 826	—	—	4 9 15	−13 1
(2) γ Eridani	3	Yellowish-red.	3 52 53	−13 46
(3) ε Persei	3	Yellowish-white.	3 50 30	+39 39
(4) δ Persei	3	Bluish-white.	3 51 6	+47 26
(5) 43 Schj.	8	Very red.	4 44 37	+28 20
(6) S Tauri	Var.	—	4 23 10	+ 9 42

Remarks.

(1) This is described in the General Catalogue as "a globular cluster, very bright, small, round, very suddenly brighter in the middle, barely resolvable (mottled as if with stars)." In 1864 Dr. Huggins observed the spectrum, and noted that it was apparently continuous, extending from the orange to the blue, without any traces of either bright or dark lines. It was again observed by Winlock at Harvard College in December 1868, and, strange to say, a bright line spectrum was recorded. "Two distinct bright lines, near each other, and coincident with air-lines λ 5020 ± and λ 4990; a third faint line λ 4900 ±" ("Harvard College Observations," vol. xiii. Part 1, p. 64). These lines were in all probability the three ordinary nebula lines near λ 500, 495, and 486. Winlock describes the nebula as planetary, and gives exactly the same co-ordinates as those given by Huggins and in the General Catalogue. If both observers really saw the same nebula, the results are highly suggestive of variability; but even then there is the difficulty of the recorded resolvability. It is quite possible that, in the four years which elapsed between the observations, the spectrum changed from an apparently continuous one to a discontinuous spectrum, by some action similar to that producing variability in such stars as Mira, but at the same time a change of brightness would also be expected, and of this there is no record. In any case, the nebula is well worthy of further examination.

(2) This star of Group II. is interesting, as being a connecting-link between stars like α Herculis, in which the bands are very wide and dark, and those like Aldebaran, in which there is a line spectrum with only the remnants of the bands in the red. Dunér states that the bands 2–8 are visible, but all of them are narrow and pale. *b*, and presumably D, are very strong. Further observations, with special reference to the lines of hydrogen, are suggested.

(3) A star, hitherto described as of the solar type, of which the usual observations are required. If the star appears to be of the same type of the sun or Capella, special attention should be directed to the presence or absence of dark carbon flutings. It is highly probable that stars like the sun, in which there is a photographic indication of carbon absorption, will subsequently cool down and become stars of Group VI., in which carbon absorption is predominant. If this be the case, all the intermediate stages of mixed metallic lines and dark carbon flutings should be represented amongst the stars.

(4) A star of Group IV., of which the usual observations are required.

(5) This is a star of Group VI. The three ordinary bands of carbon are visible, band 6, near λ 564, being rather pale. A study of Dunér's catalogue of the stars of this group shows that some of those in which band 6 is pale give secondary bands, whilst others do not. This appears to be mainly, though not entirely, due to differences of magnitude. Comparative observations with the same telescope and spectroscope, with reference to this point, are suggested.

(6) Gore states the period of this variable as 378 days, and the magnitudes at maximum and minimum as 9·9 and < 13 respectively. The colour is described as trifling, but the spectrum has not yet been recorded. The maximum will occur on December 28.

A. FOWLER.

PERIOD OF U CORONÆ.—Mr. S. C. Chandler (*Astronomical Journal*, No. 205), from the observations of the period of this star, finds an inequality of the same order as those detected in U Ophiuchi and U Cephei, variables of the Algol type. The period appears to be shortening by 0·0036s. from minimum to minimum. The results depend upon forty-five very unequally distributed minima; thirty-eight, however, lie in the interval 1870–74, and afford a basis to work upon. A larger series of observations is required to elucidate Mr. Chandler's hypothesis, which, however, is quite conformable within the limits of the purely accidental errors of the observations that have been investigated.

IDENTITY OF BROOKS'S COMET (*d* 1889) WITH LEXELL'S COMET 1770.—In the same publication as the above, Mr. Chandler gives some most interesting results of an investigation into the orbits of these comets. The following is a summary of the principal conclusions:—

(1) The encounter of the comet with Jupiter in 1886 effected a complete transformation of the comet's orbit. Instead of the present seven years' ellipse, it was previously moving in a large one of twenty-seven years' period.

(2) Several months before reaching its perihelion, it passed, near the beginning of 1886, into the sphere of Jupiter's attraction, and was deflected into a hyperbolic path about that planet, and narrowly escaped being drawn into a closed orbit, as a satellite of Jupiter.

(3) At the point of closest approach to Jupiter, May 20, 1886, the comet was distant from it only about nine diameters of the planet, passing a little outside of the orbit of the third satellite.

(4) In 1779, and not before, the comet must have come so near to Jupiter as to pass under his control and experience a radical change of orbit at the point of longitude where Lexell's comet underwent its notable disturbance in that year. Moreover, the elements of Lexell's comet before the disturbance were strikingly similar to those found for the present comet previous to 1886.

Taking all the points presented into consideration, the argument for the identity of the two comets is overwhelming. A fuller investigation will be made as soon as the observations for the whole apparition have been received.

SOME PHOTOGRAPHIC STAR SPECTRA.—An examination has been made by Dr. Scheiner of the star spectra photographed at Potsdam (*Astr. Nachr.*, No. 2923). The wave-lengths of lines in the spectra were determined by comparison with the solar spectrum, and as the probable error of the measures is estimated so small as 0·005, the identification of the lines seems beyond doubt. The following are some descriptive results:—

γ Cassiopeiæ. Continuous spectrum; hydrogen lines and D_3 bright.

α Coronæ. The magnesium line at 448·2 appears as a broad line in this star.

α Lyræ. Some fine lines, supposed to be due to iron or calcium, are seen, but have not been measured.

Sirius. 91 similar fine lines to those in the above star have been measured, and 43 ascribed to iron. Even more of these lines occur in Procyon.

α Aquilæ. The spectrum of this star appears almost identical with that of the sun.

β Orionis. The hydrogen and other lines appear broad, but are not diffused at the edges as in α Lyræ and similar stars. 20 lines have been measured from λ 400 to λ 460.

α *Aurigæ*. 291 lines have been measured in the spectrum of this star between λ 410 and λ 470, all of which appear identical with solar lines.

MAGNITUDE AND COLOUR OF η ARGûS.—Observations of this variable have been made at Cordoba since 1871, and some comparisons made by Mr. Thome (*Astr. Nachr.*, No. 2922) show that it steadily decreased in magnitude until about the end of 1886, when a minimum of 7·65 was reached, and it is now about 6·6. In 1843, Maclear gave the brightness of η Argûs as − 1·0, or between that of Sirius and Canopus, so that the variation in magnitude is 8·5, and not 6 as heretofore assumed, this variation, extending over 44 years, gives an average yearly rate of diminution of 0·2.

It is interesting to note that the change in magnitude was accompanied by a change in colour; for although before minimum the star was of a dull scarlet the colour became lighter, until in June 1889 it was a bright orange.

ORBIT OF BARNARD'S COMET 1884 II.—From an investigation of all the available observations of this periodic comet, Dr. Berberich has computed the following elements (*Astr. Nachr.*, 2938–39).

Epoch 1884 August 16·5, Berlin Mean Time.

$$
\begin{aligned}
M &= 359^\circ\ 59'\ 49''\cdot13 \\
\omega &= 301\ \ 1\ 58\cdot63 \\

Perihelion passage = 1884 August 16·516543
Period = 1972·35 ± 2·66 days.

It will be seen from the foregoing period, that the comet will be at perihelion again in 1890 January 9·87.

ALGOL.—At the meeting of the Royal Prussian Academy of Sciences, held on November 28, Prof. Vogel gave the results he had obtained from photographs of the spectrum of this variable. Prof. Pickering had pointed out, some years ago, that if the variation in stars of the Algol class were due to the transit of a dark satellite across the disk of its primary, producing a partial eclipse, then since in every case yet known the two bodies must be close to each other, and of not very disproportionate size, the primary must revolve with very considerable rapidity in an orbit round the common centre of gravity of the two; and, therefore, be sometimes approaching the earth with great rapidity and sometimes receding from it. Six photographs of the spectrum of Algol—obtained, three during last winter, and three during the November just past—have shown that before the minimum the lines of the spectrum of Algol are markedly displaced towards the red, showing a motion of recession; but that after the minimum the displacement is towards the blue, showing a motion of approach. Assuming a circular orbit for the star, and combining the details given by the spectroscope with the known variation of the star's light, Prof. Vogel derives the following elements for the system of Algol:—

Diameter of Algol...	1,074,100 English miles.
Diameter of the dark companion	840,600 „ „
Distance of centre...	3,269,000 „ „
Speed of Algol in its orbit	27 miles per second.
Speed of the companion in its orbit ...	56 „ „
Mass of Algol	$\frac{4}{9}$ of the sun.
Mass of the companion	$\frac{2}{9}$ „ „
Speed of translation of the entire system towards the earth	2 miles per second.

It will be seen that the density both of Algol and its companion is much less than that of the sun—less than a quarter, in fact. This is what we might expect, for Algol and all the variables of its class yet examined give spectra of Group IV., and should therefore represent a less advanced stage of condensation than that seen in our sun. This demonstration of the truth of the satellite theory of variation of the Algol type derives also an especial interest from Prof. Darwin's researches on tidal evolution, for assuming, as we well may, that the cause of variation is the same in all members of the class, we now know of nine stars in which a large companion is revolving round its primary at but a very short distance from it, and in a very short space of time. The companion of U Ophiuchi must, indeed, be almost in contact with its parent star.

DISCOVERY OF A NEW COMET.—A faint comet was discovered by M. Borrelly at Marseilles, on December 12, at 7h. 49·5m. G.M.T. R.A. 18h. 7m.; daily motion in R.A. + 1m. 12s. N.P.D. 41° 7′; daily motion + 60′.

GEOGRAPHICAL NOTES.

WE regret to have to record the death of Major Peter Egerton Warburton, whose name will always be intimately associated with the history of exploration in Australia. He died at Beaumont, Adelaide, in his seventy-sixth year. His most famous achievement, undertaken in 1873, was the crossing of the continent from a point on the overland telegraphic line to the De Grey River, in Western Australia. Nothing was heard of him for about twelve months, during which he and his party suffered terrible privations in their march across the desert. After the expedition, Major Warburton visited England, and was awarded a Gold Medal of the Royal Geographical Society for his efforts towards increasing our knowledge of the interior of Australia. He received the Companionship of the Order of St. Michael and St. George in 1875.

THE death is announced of Gardinal G. Massaja in his eighty-first year, at St. Georgio a Cremano. For nearly half a century the name of this distinguished explorer has been intimately associated with the progress of geographical discoveries in Abyssinia and the surrounding regions. It was at his suggestion that the Italian Geographical Society organized the Antinori Expedition to Shoa, which has resulted in the occupation of a vast region, and the extension of Italian influence over the whole of Ethiopia. His chief work, "I miei trentacinque Anni nell' alta Etiopia," abounds in valuable geographical, historical, and ethnological information on the East African regions for so many years explored and studied by him. The Cardinal was born at Piovà in 1809, and, in 1846, appointed Vicar Apostolic of the Galla nation.

FROM the Berlin Correspondent of the *Daily News* we learn that a full account of the ascent of Kilimanjaro by Dr. Hans Meyer and Prof. Purtscheller has been received at Berlin. It is dated "Marangu Jagga, October 9." The journey from Zanzibar to Uawela took exactly a fortnight. On September 25 the travellers reached Marangu. On October 2 they encamped, with a Pangani negro, on the ridge of the plateau, at a height of 14,450 feet. At 2.30 a.m. they started for the lava-ribs surrounding the valley of glaciers to the south about 1200 feet above. At 7 o'clock, on the right side of the valley, at an elevation of about 16,500 feet, the first snow was seen under cover of the rocks. The higher they went, the more clefts and fissures the field of ice had. The travellers say:—"After great exertions we reached, at 1.45, the snow-line, and it was seen that the highest peak, which was formed of rocks jutting out of the snow, was about one and a half hour's march to the left. After resting a day and a half we set off, on October 5, to bivouac in the Lava Cave, at a height of about 15,200 feet, and on the next day we repeated the ascent. The peaks were gained without particular difficulty, and on the central and highest one, 19,680 feet above the sea, the German flag was planted." Dr. Meyer proposes to call this peak Kaiser Wilhelm Peak. The view from here on to the Kibbs Crater—which is 6600 feet broad and 660 feet high, and the lower half of which is encased in a mighty belt of ice, whilst a volcanic cone of about 500 feet rises in the centre—is magnificent. The beauties of the landscape in the Kilimanjaro region seem to be quite extraordinary. On October 10 the Kimawensi was to be ascended. The two travellers enjoy the best of health.

THE double number of the *Bollettino* of the Italian Geographical Society for October and November, which appears some weeks behind time, is largely devoted to African subjects, and more particularly to the north-eastern region, which is rapidly becoming an "Italian colony." Captain D. Stasio publishes a summary of Don Francesco Alvarez's "Travels in Ethiopia" in the sixteenth century, enriched with valuable notes and additions. Alvarez, a priest attached to an embassy forwarded by Portugal, in 1520, to the Emperor of Abyssinia, shows himself a careful observer of men and things, and his work, which was included in Ramusio's "Navigationi et Viaggi" (Venice, 1588), abounds in details regarding the political, social, and economic relations of that region in the sixteenth century. Giulio D. Cocorda brings to a conclusion his important series of papers

on the South African gold-fields, which include much information on the present condition of the whole of South Africa as far north as the Zambesi. The observer points out that, while the Delagoa Bay and other lines of communication are much discussed, the fine artery of the perfectly navigable Limpopo is entirely neglected, notwithstanding Captain Chaddock's navigation of it a few years ago. The writer remarks that "this river flows mainly through regions under the influence or protectorate of England; the Transvaal people on the one side, and those of Matabeleland on the other, would certainly be glad to avail themselves of this outlet for their produce. As it traverses only a small tract of Portuguese territory about its estuary, I hope and believe that Portugal will not be allowed to treat the Limpopo as she is now attempting to treat the Zambesi. The subject is of such importance that it cannot fail soon to be brought before the British Parliament." Referring to the negotiations at present going on in connection with the Swaziland question, he observes, in the same spirit:—"The Swazi people must, sooner or later, yield either to the Transvaal or to England, and if to the former, it must be to the entire detriment of British interests. England, as the suzerain power in South Africa, should be the first in the field, both in her own interest and in that of her other colonies and subjects. If she does not assume the protectorate of Swaziland, besides losing the control of a vast and rich mineral district, she will deprive the colony of Natal of all further hope of expansion. If she ignores her responsibility in this matter, and allows the Transvaal Republic to absorb Swaziland, she will add another to the long list of blunders that threaten to destroy all prospect of consolidating a dominion as large as Canada, and may end disastrously for British interests in South Africa."

A FRENCH traveller has just achieved a feat of great interest. Captain Trivier, equipped by the newspaper *La Gironde*, started some eighteen months ago for the Congo State. He went up the river to Stanley Falls, and thence proceeded to Central Africa and the Lake region, accompanying caravans. He has just arrived at Mozambique.

Globus reports that during the past summer M. Thoroddsen, the well known student of Iceland, has carried out a journey in the waste region known as Fiskivötn, lying between Hecla and the Vatna Jökul, which has hitherto been unvisited for the most part by any inquirer. To the east and north of Hecla he discovered a new obsidian region. Crossing the Tunguaa, he went to the Fiskivötn group of lakes, all true crater lakes. The district between this and the Vatna Jökul has absolutely no plant-life whatever; it consists of lava-fields, and plains of volcanic sand. In it he found a lake, Thorisvatn, the second largest in the island. Thence, after a day's journey through an utterly desolate district, he reached the hitherto unknown source of the Tunguaa. To the south of this he discovered, between three ranges of hills, previously unknown, a new and very long lake.

MR. DAUVERGNE has, says the *Times of India*, completed an adventurous journey in the regions of North-West Cashmere. His course was from Leh northwards to the Kilian Pass, in Kashgaria, and then northwards across the Pamir to the Upper Oxus. He reached Sarhad in safety, and after six days' halt there, crossed the Hindu Kush by the Baroghil Pass, as he did not wish to visit Chitral. He then turned eastwards, and after a trying journey through the snow, crossed the Ishkaman Pass, north of Yasin. Thence he travelled southwards by the Karambar Valley, and eventually reached Gilgit, a short time after Captain Durand had started for Chitral. Mr. Dauvergne reports that the Russian explorer, Captain Grombchevsky, whose attempt to reach Kafiristan was noticed some time ago, was stopped at Kila Panjah on the Oxus, by the Afghan authorities.

THE ST. PETERSBURG PROBLEM.

THIS celebrated problem, which is first mentioned before 1708 in a letter from the younger Nicholas Bernoulli to Montmort, has been frequently discussed by Daniel Bernoulli (1730) and other eminent mathematicians. It may be briefly stated as follows:—

A tosses a coin, and undertakes to pay B a florin if head comes up at the first throw, two florins if it comes up at the second, four florins if it be deferred until the third throw, and so on. What is the value of B's expectation?

The chance of head appearing at the

1st, 2nd, 3rd, 4th . . . . nth throw is

$\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{16}$ . . . . $\frac{1}{2}^n$. A promises to pay for head

1, 2, 4, 8 . . . . 2^{n-1} florins, hence B's expectation is

$\frac{1}{2}$, $\frac{2}{4}$, $\frac{4}{8}$, $\frac{8}{16}$ . . . . $2^{n-1}/2^n = \frac{1}{2}$ florin.

Hence the total value of B's expectation is an *infinite* series, each term of which is a shilling, or it is infinite.

This result of the theory of probability is apparently directly opposed to the dictates of common-sense, since it is supposed that no one would give even a large finite sum, such as £50, for the prospect above defined.

Almost all mathematical writers on probability have allowed the force of the objection, which they have endeavoured to evade by various ingenious artifices all more or less unsatisfactory.

The real difficulty of the problem seems to lie in the exact meaning of *infinite* and *value of the expectation*.

Since the infinite value of the result is *only* true if an infinite number of trials are paid for and made, all such considerations as want of time and the bankruptcy of A or B are precluded by the terms of the question.

The value of B's expectation is frequently confused with how much he can or ought to pay for it; thus Mr. Whitworth ("Choice and Chance," p. 234) finds that if B have 1024 florins, he may give very little more than 6 florins for the venture. This ingenious, solution seems to have no reference to the original problem, which has been modified by Mr. Whitworth's introduction of the word "advantageously" (p. 232).

B can pay for his expectation in three ways: (i.) a sum before each toss; (ii.) a sum before each series of tosses ending with head; (iii.) a sum for the total result of A's operations.

Mr. Whitworth apparently assumes the first method of payment, and shows that the larger B's funds are the more he may safely pay for each toss, since he can continue to play longer. Many mathematicians take the second method of payment. "However large a fee I pay for each of these sets, I shall be sure to make it up in time" ("Logic of Chance," p. 155).

It is easy to show in this case also that what may be safely paid before each series increases with the number of series.

Suppose a very large number of tosses made, about half would come up heads and half tails; each head would end a series, when a fresh payment must be made by B. Suppose the tosses limited to one series, if B pays one florin he cannot possibly lose, if he pay anything more he may lose by head coming up the first time, and the more he pays the greater will his chance of loss be, since the series of tails must be longer to cover it. But, however large a finite sum he pays, he is not *certain* to lose, *e.g.* head *may* not come up till the hundred and first toss, when he would receive

2^{100} = 1,267 650,600 228,229 401,496 703,205 376 florins.

If the sets are limited to one hundred, about

50 heads would probably come up the			1st toss.		B would receive for each series 50 florins.
25	,,	,,	,,	2nd ,,	
13	,,	,,	,,	3rd ,,	
6	,,	,,	,,	4th ,,	
3	,,	,,	,,	5th ,,	
2	,,	,,	,,	6th ,,	
1	,,	,,	,,	7th ,,	

Hence for the hundred sets, B would receive about 350 florins, or he could pay without loss seven shillings for each set.

If N be the number of sets, the total amount received by B will probably not be less than n terms of the series

$$\left\{\frac{N \times 2^0}{2^1} + \frac{N \times 2^1}{2^2} + \text{\&c.}\right\} = n\{\tfrac{1}{2}\}N,$$

but n is the number of times which N is successively divisible by 2, or $2^n = N$, or $n = \log N/\log 2$. But the amount x which B can afford to pay per set when multiplied by the number of sets is equal to the amount which he receives, or—

$$xN = \frac{\log N}{\log 2}\{\tfrac{1}{2}\}N,$$

hence $x = \log N/0{\cdot}6$ nearly.

This formula, though inexact for low, is very convenient for high, values of N.

N = 1	x = 0	N = 10^6	x = 10
= 50	= 2·7	= 10^9	= 15
= 100	= 3·3	= 10^{12}	= 20
= 1000	= 5	= 10^{15}	= 25

x increases with, though much more slowly than, N, and becomes infinite when N does. But to justify a payment of

£50 per set, we must expect a number of sets represented by 301 figures.

Lastly, what is the value of B's expectations if A's operations are continued indefinitely. With great deference to contrary opinions, I believe this to be the correct meaning of the problem in its original form. The theoretical result is in this case easily realized by the aid of the following illustration. Suppose the person A replaced by an automatic machine similar to that used for weighing sovereigns, which tosses continuously ten times per minute. On the average of a large number of tosses, B cannot receive less than one shilling a toss, £1 every two minutes, or £720 a day for ever. If the current rate of interest be 3 per cent., he may safely pay for this perpetual annuity £8,760,000. Suppose, instead of this comparatively slow rate, the machine increased the rapidity of its operations indefinitely, the sum to be paid for the result would also increase indefinitely, or the expectation would become infinite.

SYDNEY LUPTON.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Newall Telescope Syndicate has drawn up a scheme for building a dome for the telescope on a site adjoining the present Observatory, with an observer's house; and they recommend that an observer be appointed, at a stipend of £250 per annum, with a house, to devote himself to research in stellar physics, under the general direction of the Director of the Observatory.

The results of this year's commercial examination, held by the School's Examinations Board, are satisfactory. Geography was still very imperfect. Elementary mechanics has now been added to the list of compulsory subjects.

An influential syndicate has been appointed to consider the question of the mechanical workshops, their management and utility.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 12.—"An Experimental Investigation into the Arrangement of the Excitable Fibres of the Internal Capsule of the Bonnet Monkey (*Macacus sinicus*)." By Charles E. Beevor, M.D., F.R.C.P., and Victor Horsley, B.S., F.R.S. (from the Laboratory of the Brown Institution).

After an historical introduction, the authors proceed to describe the method of investigation, which was conducted as follows: The animal being narcotized with ether, the internal capsule was exposed by a horizontal section through the hemisphere. By means of compasses the outline of the basal ganglia and capsule were accurately transferred to paper ruled with squares of one millimetre side, so that a projection of the capsule was thus obtained, divided into bundles of one millimetre square area. Each of these squares of fibres was then excited by a minimal stimulus, the same being an induced or secondary interrupted current. The movements were recorded and the capsule photographed.

In all forty-five experiments were performed, and they are arranged in eight groups, representing eight successive levels (*i.e.* from the centrum ovale to the crus) at which the capsule was investigated.

Before the results are described in detail a full account is given of previous investigations, experimental, clinical, and anatomical, on the arrangement of the internal capsule.

The anatomy of the part and the relation of the fibres to the basal ganglia are then discussed, and a full description given of each of the groups examined.

The general results are next given at length, of which the following is a *résumé*.

Firstly, the rare occurrence of bilateral movement is discussed, and the meaning of the phenomenon defined. Secondly, the lateral arrangement and juxtaposition of the fibres are considered. Thirdly, the antero-posterior order in which the fibres for the movements of the different segments are placed is described, and that order found to be practically identical with that observed on the cortex, viz. from before back:—

Movements of eyes.
head.
tongue.
mouth.
upper limb (shoulder preceding thumb).
trunk.
lower limb (hip preceding toes).

The character or nature of these movements is set out in a table giving the average localization of each segment. Speaking generally, it may be said that the movements are arranged in the same way as has already been shown by the authors to exist in the cortex (*vide* previous papers in Phil. Trans., 1887, 1888), viz. that the representation of extension is situated in front of flexion for the segments of the upper limb, while for the toes flexion is obtained, as in the cortex, in front of extension.

Numerous tables and diagrams are appended, showing the extent of appropriation of fibres for each movement.

Physical Society, November 15.—Prof. Reinold, F.R.S., President, in the chair.—Mr. Enright resumed the reading of his paper on the electrification due to contact of gases with liquids. Repeating his experiments with zinc and hydrochloric acid, the author, by passing the gas into an insulated metallic vessel connected with the electrometer, proved that it was always charged with electricity of the opposite kind to that of the solution. The electrical phenomena of many other reactions have been investigated, with the result that the gas, whether H, CO_2, SO_2, SH_2, or Cl, is always electrified positively when escaping from acids, and negatively when leaving a solution of the salt. In some cases distinct reversal is not obtainable, but all these seem explicable by considering the solubility and power of diffusion of the resulting salts. Various other results given in the paper tend to confirm this hypothesis. Seeking for an explanation of the observed phenomena, the author could arrive at no satisfactory one excepting "contact" between gases and liquids, and if this be the true explanation he hoped to prove it directly by passing hydrogen through acid. In this, however, he was unsuccessful, owing, he believes, to the impossibility of bringing the gas into actual contact with the liquid. True contact only seems possible when the gas is in the nascent state. Some difficulty was experienced in obtaining non-electrified gas, for the charge is retained several hours after its production, even if the gas be kept in metallic vessels connected to earth. Such vessels, when recently filled, form condensers in which the electricity pervades an inclosed space, and whose charge is available on allowing the gas to escape. Soap bubbles blown with newly generated hydrogen were also found to act as condensers, the liquid of which, when broken, exhibited a negative charge. This fact, the author suggested, may explain the so-called "fire-balls," sometimes seen during thunderstorms; for if, by any abnormal distribution of heat, a quantity of electrified air becomes inclosed by a film of moisture, its movements and behaviour would closely resemble those of fire-balls. A similar explanation was proposed for the phenomenon mentioned in a recent number of NATURE, where part of a thundercloud was seen to separate from the mass, descend to the earth, and rise again. The latter part of the paper describes methods of measuring the contact potential differences between gases and liquids, the most satisfactory of which is a "water dropper," and by its means the P.D. between hydrogen and hydrochloric acid was estimated to be about 42 volts. Prof. Rücker asked if the experiment with zinc and hydrochloric acid could be started in the second stage by having the acid partly saturated with salt. Dr. C. V. Burton thought it probable that contact could be made between a gas and a liquid by shaking them up together in a bottle. In reply, Mr. Enright said the experiment could be started at any stage, and reversal effected as often as desired by adding either acid or a solution of salt to the generating vessel.—Mr. Herbert Tomlinson, F.R.S., read a paper on the effect of repeated heating and cooling on the electrical resistance and temperature coefficient of annealed iron. In a paper recently presented to the Royal Society, the author has brought forward an instance of an iron wire, which when subjected to magnetic cycles of minute range alternately at 17° and 100° C., had its molecular friction and magnetic permeability reduced respectively to about one-quarter and one-half their original values. The present experiments were undertaken to see whether by

such heatings and coolings the temperature coefficient of iron could be brought down to something approaching the number given by Matthiessen for "most pure metals." The wire experimented on was first annealed by heating to 1000° C. for several hours and allowing to cool slowly in a furnace placed at right angles to the magnetic meridian; the process was repeated three times. Afterwards the wire was covered with paper and wound doubly into a coil. This coil was inclosed in a water-jacketed air-chamber, and connected with a sensitive Wheatstone bridge. Thermo-electric and Peltier effects were eliminated by always keeping the galvanometer circuit closed. By repeated heating to 100° C. and cooling to 17° C. for long intervals, the specific resistance at 17° C. was reduced from 11,162 to 10,688 C.G.S. units, after which the operations produced no further change. At the same time the temperature coefficient increased in the proportion of 1 : 1·024. From careful determinations of the resistance at different temperatures, the formula $R_t = R_0(1 + 0·005131t + 0·00000815t^2)$ was deduced, whilst that obtained from Matthiessen's results for pure iron annealed in hydrogen is $R_t = R_0(1 + 0·005425t + 0·0000083t^2)$. Taking his own determination of specific resistance of impure iron as correct, coupled with Matthiessen's law connecting the resistances and temperature coefficients of metals and their alloys, the author finds that the specific resistance of pure iron deduced from Matthiessen's results is from 4 to 5 per cent. too high. In conclusion, Mr. Tomlinson expresses a hope that the B.A. Electrical Standards Committee may be induced to determine the absolute resistance and temperature coefficient of the pure metals which are in ordinary use. Prof. Ayrton thought Matthiessen's results were expressed in B.A. units, and hence might appear 1 or 2 per cent. too great. Mr. Tomlinson, however, believed the number he took were expressed in legal ohms. Dr. Walmsley asked for what value of the magnetizing force the permeability of the iron mentioned in the beginning of the paper was determined; to which Mr. Tomlinson replied that they were much smaller than the earth's horizontal component.—Dr. Thompson's paper on geometrical optics was postponed.

Edinburgh.

Royal Society, December 2.—Sir Douglas Maclagan, Vice-President, in the chair.—Prof. Tait communicated a paper by Dr. G. Plarr, on the transformation of Laplace's coefficients.—Mr. A. C. Mitchell read a preliminary note on the thermal conductivity of aluminium. A comparatively rough first experiment shows that this metal slightly exceeds good copper in conducductivity.—Dr. John Murray discussed the question of the origin and nature of coral reefs and other carbonate of lime formations in recent seas. He first referred to experiments which have recently been made regarding secretion and solution of carbonate of lime. Carbonate of lime remains are found in great abundance at the sea bottom in shallow waters, but the amount steadily diminishes as the depth increases, until at 4000 fathoms almost every trace has disappeared. This is due to solution, as the organisms slowly fall to the bottom. Everywhere within 500 fathoms of the surface the ocean teems with life. The Greely Expedition was starving within ten feet of abundant food which might have been obtained by breaking a hole through the ice and using a shirt as a drag-net. Dr. Murray then proceeded to discuss his theory of the formation of coral reefs, bringing forward in reply to objections by Dana and others, some recently obtained facts regarding the existence of shallow regions in what is, on the whole, deep water. He showed that carbonate of lime is continually produced in great quantity in warm tropical water by the action of sulphate of lime in solution on effete products. This explains the great growth of coral in tropical regions. The absence of coral on certain shores in tropical districts is explained by the uprise of cold water due to winds blowing off shore. His paper was illustrated by an elaborate series of lime-light diagrams.

Paris.

Academy of Sciences, December 9.—M. Hermite in the chair.—On the nitrification of ammonia, by M. Th. Schlœsing. In a recent communication (September 9) the author described three experiments on the nitrification of ammonia in vegetable humus, tending to prove that this phenomenon is accomplished without any appreciable loss of nitrogen liberated in the gaseous state. He now reports the results of two other experiments, showing that this is no longer the case when a larger proportion of ammonium carbonate is introduced into the soil.—Correction in the tables of Jupiter's movement worked out by Le Verrier, by M. A. Gaillot. Comparing the secular terms of the eccentricity and perihelion of Jupiter's and Saturn's orbits as determined by Le Verrier, Hill (*Astronomical Journal*, No. 204) came to the conclusion that there must be an error of sign in the terms of the second order relating to Jupiter's orbit. M. Gaillot has now gone over the calculations again, and finds that Le Verrier's manuscript is correct, but that, as conjectured by Hill, a misprint of a sign occurs in the published work. In vol. x. p. 242, the sign + appears instead of – before the term $0''·015,554\beta' \cos(\omega - \pi')$.—On the characteristic temperatures, pressures, and volumes of bodies, by M. Ladislas Netanson. These researches tend to show that for every gas there exists an infinite number of characteristic values, *t*, *p*, *v*, which, being adopted as units of the general variables *t*, *p*, *v*, have the remarkable property of eliminating all difference in the characteristic equations of the different gases. The systems usually employed in measuring temperatures, pressures, and volumes, having nothing in common with the intimate nature of the bodies themselves, give rise to differences in the equation $F(t, p, v) = 0$, which disappear when for each body the physicist employs a special system in accordance with its properties.—On the localization of the interference fringes in thin isotropic plates, by M. J. Macé de Lépinay. In studying the exact conditions of the fringes in thin prismatic plates, the author finds a complete verification of the general theory expounded by him in a previous communication (*Comptes rendus*, July 22, 1889). The consequences of the theory may be considered as entirely verified by these experiments.—On the want of accuracy in thermometers, by M. E. Renou. On a recent occasion (July 1) M. Cornu remarked that hitherto these instruments have been liable to an error of from 0°·2 to 0°·3. It is now shown that observations hitherto recorded may give rise to the greatest inconvenience, more perhaps in future than at present. These remarks were supplemented by M. Cornu, who pointed out that errors in the mercury thermometer as great as 0°·2 or 0°·3 occur only in observations taken at considerable intervals of temperature and with instruments not sufficiently tested.—Variations in the mean temperature of the air at Paris, by M. Renou. Twenty years ago the author attempted to show that severe winters return in groups of five or six every forty-one years. This somewhat elastic period is perhaps reproduced better in groups of years than in single years. It also appears that the Observatory of Paris gives a mean temperature higher by 0°·7 than that of the surrounding rural districts—10°·7 as compared with 10°·0 of the Parc Saint-Maur Observatory.—On the observations of temperature on the top of the Eiffel Tower, by M. Alfred Angot. These observations, begun on July 1, are being still continued with a Richard registering thermometer, placed 336 metres above the sea, and about 301 above the ground. Compared with those of the Parc Saint-Maur (50 metres) they show that the normal decrease of about 1° for every 180 metres is greatly exceeded in summer and during the day (means of the maxima), and correspondingly diminished in winter and at night (means of the minima); or there is generally even an inversion in the temperatures, the air being then warmer at 300 metres than near the ground.—Papers were submitted by M. Raoul Varet, on the ammoniacal cyanides of mercury; by M. L. Prunier, on the simultaneous quantitative analysis of sulphur and carbon in substances containing sulphur; by M. E. Guinochet, on an acid isomerous with tricarballylic acid; by M. C. Tanret, on two new sugars extracted from quebracho (*Aspidosperma quebracho*); by M. Arnaud, on carotine, its probable physiological action on the leaf; and by MM. André Thil and Thouroude, on a micrographic study of the woody tissues of native trees and shrubs, prepared for the special exhibition of the Forest Department.—The sealed paper, by M. A. Joannis, on compounds of potassium and sodium with ammonia gas, was opened by the Secretary.

Berlin.

Physical Society, November 22.—Prof. du Bois Reymond, President, in the chair.—Dr. Lehmann spoke on the nature and distribution of the Babylonian metrical system. He expressed his desire to lay before the competent judgment of the Physical Society, the results of his most recent archæological researches, so far as they are of direct physical interest, and then proceeded to describe the numerical system employed by the ancient Baylonians, explaining that it consisted of a sexagesimal system with decimal subdivisions. The unit of time, the double-

minute, was the time occupied by the sun's rising, measured at the Equinox, and could thus be recovered at any time. It was measured by the mass of water which flowed out of a certain vessel from the instant at which the upper edge of the sun appeared above the horizon to the moment at which his lower edge was exactly touching the horizon. The day consisted of 720 of these units. The unit of length was the ell, which was used in two forms, either as a single- or double-ell; subdivisions used were the foot = ⅓ double-ell, the hand-width, and the finger-length. The unit of weight was the mine, also occurring as single-mine or double-mine. The derivation of units of weight from units of length, as in the modern case of grams and centimetres, was also known, but of course the water used was not distilled and was not weighed at 4° C. The speaker had, however, succeeded in discovering a measuring-scale on an ancient monument dating from the year 2500 B.C., which had enabled him to compare the Babylonian measures with those of our own time. It appeared from this that a hand-breadth = 99·4–99·6 mm.; a double-ell = 994–996 mm.; and the foot = 331–332 mm. He had further discovered several stamped weights, and thus found that the double-mine = 982·4–985·8 grams. The single-mine weighed half as much as the double-mine, but the gold-mine and silver-mine were equal to five-sixths of a single-mine. The royal-mine was 1 per cent. heavier than the gold-mine, and was employed for the payment of tribute. The coinage was based upon the mine and its sexagesimal division. Dr. Lehmann remarked how surprising it is to find that the length of a seconds-pendulum at Babylon is 992·5 mm., and was inclined to advance the hypothesis that the Babylonian unit of length was derived from a seconds-pendulum, the foot being one-third the length of the pendulum. He next proceeded to give an account of the spread of the Babylonian mine, and of the Phœnician which was derived from it, as a unit of weight among the civilized nations of Europe. The discovery of an old Roman balance had enabled him to determine that the old Etrurian pound was equal in weight to the Babylonian mine. The Babylonian unit of weight is found not only in Italy and the Mediterranean generally, but also the old Dutch and French pounds and the Russian pood are equal in weight to the mine. The speaker considered it to be quite impossible that in all the above cases we are dealing with a chance correspondence between the several weights. In the discussion which ensued, objections were raised on several sides against the hypothesis that the ancient Babylonians had knowledge of the seconds-pendulum, which had subsequently been lost. On the other hand, it was pointed out by others that the ancients were not improbably acquainted with the plummet, and used it for squaring stones, &c.; and since, further, they employed the double-minute as unit of time, it is not impossible that they were acquainted with the seconds-pendulum. The cause of their not having employed this instrument to supply a time-unit may perhaps be found in their ignorance of any means by which the pendulum could be kept in continuous and uniform motion. In conclusion, the speaker laid stress on the high state of culture which the Babylonians had attained three thousand years B.C., and expressed his regret that a complete blank exists with regard to everything of an earlier date than the cuneiform inscriptions.

RECENT ORNITHOLOGICAL WORKS.

Notes on Sport and Ornithology. By His Imperial and Royal Highness the late Crown Prince Rudolph of Austria. Translated, with the Author's permission, by C. G. Danford. Pp. i.-viii., 1-648. (London: Gurney and Jackson, 1889.)

Matabele Land and the Victoria Falls. A Naturalist's Wanderings in the Interior of South Africa. From the Letters and Journals of the late Frank Oates, F.R.G.S. Edited by C. G. Oates, B.A. Second Edition. Pp. i.-xlix., 1-433. (London: Kegan Paul, Trench, and Co., 1889.)

Index Generum Avium. A List of the Genera and Subgenera of Birds. By F. H. Waterhouse, A.L.S. Pp. i.-v., 1-240. (London: R. H. Porter, 1889.)

The Birds of Oxfordshire. By O. V. Aplin. With a Map. Pp. i.-vii., 1-217. (Oxford: Clarendon Press, 1889.)

The Birds of Berwickshire; with Remarks on their Local Distribution, Migration, and Habits, and also on the Folk-lore, Proverbs, Popular Rhymes, and Sayings connected with them. By George Muirhead, F.R.S.E. Vol. I., pp. i.-xxvi., 1-334. (Edinburgh: David Douglas, 1889.)

The Birds in my Garden. By W. T. Greene, M.A., M.D. (London: Religious Tract Society, 1889.)

NO naturalist can peruse the pages of the handsome volume which contains the record of the sporting journeys of the late Crown Prince Rudolph, without sincere feelings of pity and regret. Here was a young man, whose scientific instincts were of the truest, and for whom, in every way, a splendid future might have been predicted, whose opportunities for the advancement of science were unlimited; and it is most sad that so promising a life should have been cut short by the decrees of fate. One-third of the volume before us is devoted to "Fifteen Days on the Danube," and the narrative affords a striking experience among the varied forms of bird-life which are to be met with on that famous river in April. This is a really valuable sketch of the ornithology of the district, and will be useful to everyone who is interested in the distribution of European birds. The same may be said of the chapters entitled "Sketches of Sport in Hungary" (pp. 391-98), "Miscellaneous Notes on Ornithology" (pp. 409-54), "Ornithological Sketches in Transylvania" (pp. 559-72), and the various "Ornithological Notes" from the neighbourhood of Vienna, &c. Throughout the work the great affection which the author entertained for the birds of prey is manifested, and the "Ornithological Sketches from Spain" (pp. 455-502), are entirely devoted to Raptorial birds, as are also many other chapters in the book. Prince Rudolph thoroughly believed in the races of Golden Eagle (*Aquila chrysaëtus*), which are admitted by A. E. Brehm and other Continental authors. The "Stein" Eagle is generally supposed to be a distinct bird from the true Golden Eagle, and we remember how the Crown Prince overhauled the series of specimens in the British Museum, and pointed out the differences between the supposed races; but when the discussion was over, we could only see that the "Stein" Eagles consisted mostly of immature birds, while the "Golden" Eagle was represented by the older birds in the collection, the alleged difference of habitat being due to the fact that the more lowland country frequented by the "Stein" Eagle was due to their being driven from the mountain eyries by the older birds. The discussion of many points by the Crown Prince on his visit to the British Museum was sufficient to show what a thoroughly sound ornithologist he was. Mr. Danford has done his work as a translator with evident care and a sympathetic knowledge of his subject. Over much of the ground traversed by the Prince the translator has also travelled, and he has evidently fully appreciated the enthusiasm of the author. In the "Ornithological Sketches from the East," wherein are detailed the results of the Crown Prince's journeys in Egypt and Nubia, and afterwards in Palestine, we notice several identifications which strike us as remarkable, and which we believe to be wrong Was not *Falco feldeggii*, the Lanner Falcon, the species identified by the Prince as *F. barbarus? Acrocephalus turdoides* (p. 513). Surely this is *A. stentoreus? Certhilauda duponti*, "seen in considerable numbers, but only among the bushes and scattered pastures of the islands near the Barrage of the Nile." We should like some confirmation of such an eastward extension of this Algerian bird's range. Generally, however, the nomenclature is good, though slightly Brehmian in character and Mr. Danford has detected some obvious errors, though the above statements appear to have escaped him.

The late Mr. Frank Oates was a young naturalist who travelled in South Africa in 1873, 1874, and 1875, and died from fever in February of the latter year after his return from the Zambesi. He was a fine specimen of the English traveller, devoted to the pursuit of natural history, and gifted with indomitable perseverance and pluck. His intention on going to South Africa was to penetrate into the interior beyond the Zambesi, and he seems to have regarded his Matabele journey as but a preliminary to more important explorations. The difficulties, however, of getting to the Victoria Falls were very great, and the traveller only succeeded in reaching this desired goal after four attempts and after excessive difficulties and delays. He seems to have won the friendship of Lobengula, and readily obtained the support of the latter for his expedition, but the inferior chiefs and the natives generally were very troublesome. The narrative shows that at the date of Frank Oates's expedition it was by no means easy to get to the Zambesi, especially when the traveller was bent upon collecting *en route*. He gave himself no rest in his pursuits; and the attack of fever which carried him off at the very time when one of his brothers was on the way to join him in the interior was doubtless accentuated and rendered fatal by his untiring devotion to work, which seems to have been one of his most pronounced characteristics. After the traveller's death, a friend, Mr. Gilchrist, went into the interior and brought down all Oates's effects and his natural history collections, and the story of the expedition was originally told by his

brother, Charles Oates. The collections were worked out by different naturalists, and the whole results embodied in appendices which were, moreover, thoroughly well illustrated. Scarcely had the book appeared and met with a cordial appreciation from the public, when a fire at the publishers' destroyed the whole of the unsold copies; and now, after a lapse of some years, Frank Oates's brother and faithful biographer, Charles Oates, has brought out a second edition. Although the necessity of residing abroad has prevented the latter from finishing his labour of love before the present year, the work has lost nothing in consequence. The narrative must always remain of value as a simple record of a naturalist's journey, and the maps of the route are laid down with a fidelity and minuteness not to be exceeded if the traveller had been on a cycling tour instead of in the wilds of Matabele Land, while the lapse of time has enabled the authors of the various appendices to give additional information, to correct errors, and generally to bring their work up to date. Several species undetermined in the first edition have now been identified and described, new plates have been added, and the results as now given to the public by Mr. Charles Oates form a very material and valuable contribution to our knowledge of the natural history of Southern Africa, with the development of which the name of Frank Oates will be for ever connected. All the authors of the various appendices—the late Prof. Rolleston (to whose memoir Mr. Hatchett Jackson, of the Oxford Museum, has added some further information), Prof. Westwood, Mr. Distant, Mr. Olliff, and Mr. Rolfe—seem to have been actuated by a desire to work out the collections intrusted to them for description with the utmost care; and the present writer can only say that the writing of the ornithological portion of the volume was not only a pleasing task, but took the form of an absolute duty to do justice to the memory of the traveller, and to aid Mr. Charles Oates in his fraternal enthusiasm for his brother's fame. Would that every traveller in the Dark Continent attached as much importance to its natural history as did Frank Oates, and that the work of each one was edited by a loving friend, possessed of a desire to place on record the scientific results of the expedition, as has been done in the present work, so that volumes of travel, important as they are, might be rendered still more valuable by biological appendices such as are to be found in Oates's "Matabele Land."

Mr. F. H. Waterhouse, the well-known Librarian of the Zoological Society, has just issued a very useful book, which supplies a great want. The splendid library under his charge has given him the opportunity of personally verifying his references, and many inaccuracies which had been copied from one author to another are herein set right. He has applied himself so diligently to his task, that we believe that about 500 names, of which the origin was obscure, have been traced by the industrious author to their original source, and this fact alone should commend the work to the attention of every working ornithologist. It should be mentioned, however, that Mr. Waterhouse does not pretend to be a practical ornithologist, and he has been dependent to a great extent upon the *Zoological Record* for recent additions. As the volume for 1887 appeared only while the present work was going through the press, several new genera proposed in that year do not find a place in Mr. Waterhouse's book, and therefore the student who interleaves his copy must begin with the *Record* of 1887 if he wishes to have a complete "catalogue" of ornithological generic names.

Of the making of county lists of birds there is apparently no end, and "a good job too!" Little by little, enthusiastic observers are compiling ornithological lists for the different counties of the British Islands, and by these means alone can we hope to obtain a thoroughly accurate knowledge of the distribution of the birds of Great Britain. Mr. O. V. Aplin has long been known to us as an excellent observer, and we hope that the success of his first work, the results of several years of assiduous labour, will encourage him to still more ambitious efforts. The somewhat irregular shape of the county of Oxfordshire, and its generally narrow diameter, preclude the anticipation of a very varied avifauna; but the record of 242 species for the district is by no means bad, and some very interesting notes are given, the principal rarity being the Alpine Chough, of which the only British occurrence has taken place in Oxfordshire, and of which a good plate, by Mr. S. L. Moseley, is given. One of the most inviting features of Mr. Aplin's book is its conciseness. In the capital introduction he gives a very complete account of the configuration of the county and its natural features, all of which can be easily studied with the aid of the excellent map which accompanies the work.

A more ambitious volume is Mr. Muirhead's "Birds of Berwickshire," which is got up in a Bewickian style, as a book matured in such close proximity to Northumberland should be. Mr. Muirhead's book is a complete exemplification of that better style of county record which has been the order of the day during recent years, when a sober statement of facts of distribution and habits has taken the place of strenuous efforts to record rare, and often impossible, visitants. After an introduction which deals with the physical features of the county, aided by a very clear map, the author gives an account of the birds, from the Thrushes to the end of the Accipitres. The accounts of these birds not only contain ample, yet concise, information, but are interspersed with poetry, of a Scottish and local flavour, which successfully combats any notion of dulness, while the folk-lore of the district appears to have special attractions for the author. In some instances, notably that of the Rook, very full details of the breeding-haunts are given in tabular form. It is interesting to note how, on the border-lands, some species have increased in numbers, and have gradually extended their range towards Scotland. The illustrations of nests are drawn by Mrs. Muirhead, and very good they are; and the book is replete with woodcuts by Mr. John Blair, aided by some excellent reproductions of etchings by W. D. M'Kay, R.S.A., and other well-known artists. We trust that in the second volume Mr. Muirhead may be tempted to give us a few details respecting some of the places illustrated in the text, that his readers may share the evident pleasure with which he has illustrated some of the interesting localities of Berwickshire.

Dr. W. T. Greene's little work, "The Birds in my Garden," is an entertaining idyll of a London suburb. Many of the author's experiences agree with our own, and such a book as the present is just the one to encourage a love for the birds which are still to be seen in

the vicinity of London, although, as the operations of the builder are extended in every direction year by year, their number gradually, but surely, diminishes. Where Dr. Greene writes from his own experience, he is always worth listening to, but he has a faith in Morris, which, as might be expected, often leads him awry. He quotes from the Bible about the "Sparrow" on the house-top (p. 13), but the bird alluded to is the Blue Rock Thrush (*Monticola cyanea*), for which cf. Canon Tristram's "Fauna and Flora of Palestine" (p. 31). The illustration on p. 23 is not that of the common Sparrow, but of the Tree-sparrow. At p. 46 he gives a tabular list of characters by which to distinguish the Missel-thrush from the Song-thrush, in which the former bird is said to have "no song to speak of." Evidently, Dr. Greene has never heard a "Storm-cock" in full swing. He does not love the Greenfinch, but this need not lead him to say that the species likewise "has no song." A cock Greenfinch, perched on the top of a tree in the nesting season, and singing to his mate sitting on the nest below, has a charming and varied song, like that of a very powerful Canary. The Whitethroat, of which Dr. Greene appears to know only one species, is placed in the sub-family *Motacillidæ*, and it will surprise many ornithologists to hear that the song of the Chiff-chaff is continued even till late in September (this information is derived from the Rev. F. O. Morris !). The Blackcap does *not* winter in Eastern Africa, and it can hardly be said that the Siskin "rarely nests in this country." We mention these points at the risk of appearing hypercritical, but we recognize in Dr. Greene an author who has the knack of writing good natural history books for the young, and it is therefore the more incumbent upon him to be scrupulously accurate. Let him discard Morris, and stick to Seebohm's "History of British Birds," or to the new edition of "Yarrell." Some pretty illustrations by Mr. Whymper form an additional attraction to his little book.

R. BOWDLER SHARPE.

DESCARTES.

History of Modern Philosophy. "Descartes and his School." By Prof. Kuno Fisher. Translated by J. P. Gordy, Ph.D., and edited by Noah Porter, D.D., LL.D. (London: T. Fisher Unwin, 1887.)

AMONG the many histories of modern philosophy few are so interesting and attractive as that by Prof. Kuno Fisher. The present volume consists of a translation of the third revised German edition, which includes the period of Descartes and his school; and the admirable way in which the author deals with so difficult a subject and his boldness in overcoming it are worthy of the highest praise.

The book is divided into three parts, the first of which is preceded by an introduction to the subject, showing the course of development of the Greek philosophy and that of the Middle Ages, with an account of the early history of Christianity and the Church, concluding with the periods of the Renaissance and the Reformation.

In Part I. we have an account of the early history of Descartes. He was born in the year 1596, a few days before the death of his mother, and was a weak and sickly child. Throughout his childhood he showed a strong desire for knowledge, and it was on this account that his father called him his "little philosopher."

Descartes was among the first pupils in the new school that was started at the Royal palace at La Flèche by Henry IV.; at the age of seventeen he was committed to the care and tutorage of Father Dinet. During his school life he was among the chosen pupils who, on June 10, 1610, solemnly received the heart of the king, which, by Henry's will, was to be buried in the church of La Flèche.

While going through a two years' course on philosophy, he became completely fascinated by mathematics, and was thereby incited to make a further study of it; and later on in life, seeing the true spirit of mathematics as a method of solving problems, he began by algebraical equations to solve geometrical problems, and thus to him is due the discovery of analytical geometry. On the completion of his school career, the state of his mind may be gathered from his own words—" . . . I found myself involved in so many doubts and errors, that I derived no other result from my desire of learning than that I had more and more discovered my own ignorance."

The next few years of his life were spent in military service in Holland and Germany, after which, at the age of five-and-twenty, he travelled for nine years; to him his travels were studies in the great book of life, and during them he "did nothing but wander now here, now there, since I wished to be a spectator rather than an actor in the dramas of the world." The last period of his life consisted of the development and publication of his works, and the founding of a school of philosophy, concluding with his illness and death during his stay in Stockholm, to which place he was invited by Christina, then Queen of Sweden, who, being deeply interested in his works, found the difficulties in his system could better be explained by Descartes himself than by anyone else.

Although the philosophy of Descartes treats of the whole realm of Nature, we will here touch only upon those parts that are interesting to us from the scientific point of view. Not by any means the least important is his attempt to explain the origin of the world by purely mechanical laws. He bases his theory on the rest and motion of solid and liquid bodies, and the influence of the latter upon the former. Before entering upon this hypothesis, the mechanical principle of his explanation of Nature is first brought before us. He treats motion as a mode of extension, and explains it as the "translation of place (transport) of one part of matter or of one body from the vicinity of those bodies which directly touch it, and are considered at rest, into the vicinity of others."

The causes of motion are next dealt with, showing us that all changes are due to outward collision, and that since space is by no means empty, but is full of bodies moving in every direction, we may get a great number o collisions, the various possible results of which he then goes on to discuss. According to his principles, then, bodies are quite destitute of force, excepting that of resistance; changes in the material world are due to external collisions, and motion, therefore, is due to impacts. Comparing the views of Descartes with those of Galileo and Newton, we cannot do better than quot

what the author says on this point:—"Gravity is regarded as . . . . an original property of a body belonging to it of itself. Descartes denies it. Therein consists the opposition between Galileo and Descartes; with gravity he was obliged to reject gravitation and the power of attraction. Therein consists the subsequent opposition of Newton and Descartes; he is, therefore, compelled to deny the so-called central forces, as well as every *actio in distans*."

The two essential pre-suppositions of his hypothesis are the "immeasurableness of the universe and the nullity of empty space. From the first it follows that the universe is not a spherical body, and does not consist in concentric spheres to which the stars are fastened; that there is, therefore, no celestial sphere beyond the farthest planet (Saturn), and that the sun does not lie in the same spherical superficies. From the second, it follows that the spaces of the heavens are filled with fluid matter, and that the heavenly bodies are surrounded by the latter, and subject to its influences."

Descartes supposes the earth to be completely surrounded by this fluid, and "acted upon uniformly in every direction, or carried along by its current, as a solid body in liquid matter. The planets follow also the same rule. Each is at rest in the heavens in which it is, and all the change of place which we observe in those bodies follows from the motion of the matter of the heavens which surrounds them on all sides."

By supposing, again, that this flow of the matter, which surrounds the earth and planets, describes a current "spinning round like a vortex," with the sun in the centre and the earth and planets going round it; he obtains, without considering their weight and attraction, a method by means of which their various motions may be explained. He compares this "vortex" motion of the matter with eddies of water, "as waters when they are forced to a reflux form an eddy, and draw violently within their rotary motion, and carry along with them, light floating bodies, as, for example, straws; as then these bodies, seized by the eddy, turn about their own centre, and those nearer the centre of the eddy always complete their rotation earlier than the more distant ones; as, finally, this eddy always, to be sure, describes a circular figure, but almost never a perfect circle, but extends itself, now more in length and now in breadth, wherefore the parts at the periphery are not equally distant from the centre,—so one can easily see that the motion of the planets is of the same character, and that no other conditions are necessary to explain all their phenomena."

Thus Descartes agrees with Copernicus and Galileo with regard to the heliocentric motion of the earth and planets, although basing his hypothesis on different mechanical laws; he also teaches that the earth is a planet, and rotates on its axis daily, and revolves yearly in an elliptical orbit round the sun.

The author then tells us how Descartes, after the completion of his hypothesis, postponed its publication, on account of the fate of Galileo, and how he (Descartes) expressly stated at the end that "his hypothesis not only may be, but in certain respects is, false." Although he denied the movement of the earth, it was only in a sense that followed from his idea of motion which he applied to the heavenly bodies; for, with reference to the other bodies in the heavens, it does move, but is at rest in relation to the fluid matter around it, or, as the author says, "it moves exactly as a man who is asleep in a ship, while it takes him from Dover to Calais."

In conclusion, we must add that the work of both translator and editor has been honestly done, though, as the above quotation shows, the style of the translator is susceptible of improvement, and that this volume will form a valuable addition to the libraries of students of moral philosophy. To the readers of such a work as this, consisting as it does of so many historical facts, an index is imperative, and we hope in future editions to see one inserted.

W. J. L.

A TEXT-BOOK OF ORGANIC CHEMISTRY.

A Text-book of Organic Chemistry. By A. Bernthsen, Ph.D., formerly Professor of Chemistry in the University of Heidelberg. Translated by George McGowan, Ph.D., Demonstrator in Chemistry, University College of North Wales, Bangor. (London: Blackie and Son, 1889.)

THIS work furnishes an excellent elementary account of the principles of organic chemistry. An introduction treating of the general theory of organic compounds, including the subjects of constitution, isomerism, physical properties, &c., is followed by the detailed description of the various classes of compounds and their relations to one another, the fatty compounds being first discussed, and then those belonging to the group of aromatic substances and to the pyridine group. The treatment of the various compounds in "series," all the hydrocarbons of the fatty series—paraffins, olefines and acetylenes—being, for example, fully described before any of their halogen derivatives or of the alcohols are discussed, cannot be commended from the point of view of the novice to the science, for whom the book is avowedly designed. This evil is, however, largely compensated for in the present work by the clear language invariably employed, and more especially by the frequent introduction of semi-diagrammatic tables showing the connection between various related series, such, for example, as the glycols, hydroxy-acids and dibasic acids.

The description of the aromatic compounds, prefaced by a short account of the benzene theory, is grouped about the typical hydrocarbons, benzene and its derivatives being first treated, then diphenyl with its derivatives, triphenyl-methane and its group, naphthalene, &c. Mere description of compounds is sternly and consistently avoided, its place being supplied, whenever possible, by tabulated statements, showing at a glance both the chemical and physical relations of a whole series of derivatives. These tables are a distinguishing feature of the book, and impart to it a clearness and conciseness which will render it welcome to every student.

Abundant references are provided to the original papers concerning subjects which fall without the elementary scope of the work, such as, among many others, the diazo-derivatives of the fatty series, the syntheses of glucosides, and the grouping of atoms in space, which last is treated in language which will perhaps be apt to mislead, and scarcely receives a degree of attention commensurate with its importance.

The translator has performed his work with great success, and he is to be congratulated on the almost complete absence of printers' errors, which so often mar the pages of works of this class. It is to be regretted that he has in some instances neglected to adopt the nomenclature employed by the Chemical Society, since uniformity of usage in this respect is greatly to be desired. An excellent index forms a fitting conclusion to the work, which is sure to take as high a place among the elementary text-books of organic chemistry in the English language as it has already done in the Fatherland.

OUR BOOK SHELF.

The Viking Age; the Early History, Manners, and Customs of the Ancestors of the English-speaking Nations. By Paul B. Du Chaillu. Two Vols. 1366 Illustrations, and Map. (London: Murray, 1889.)

THE author of this work has persuaded himself that the invaders who conquered and settled in Britain after the departure of the Romans were not, as we have been taught to believe, Low Dutch tribes, but Norsemen. It is unfortunate that he should have hampered himself in his researches by so arbitrary a theory. Of course, no one disputes that there is a strong Scandinavian element in England; the fact has always been perfectly well understood by historians, and has received from them due attention. But to say that the English people are wholly or mainly descended from Scandinavians is to advance a proposition opposed to all the most vital evidence we possess on the subject. The evidence of language alone would suffice to dispose of so crude a doctrine. Mr. Du Chaillu has not approached the consideration of the question in a scientific spirit, and has too lightly brushed aside the difficulties in his way.

He has tried to give an account of the ideas, customs, manners, and institutions of the ancient Scandinavians; and we need scarcely say that there are some lively and attractive passages in his chapters on these subjects. From his book, English anthropologists will learn that there is valuable material for them in the old northern laws and Icelandic Sagas. They will, however, be unable to make use of his translated extracts, because he does not attempt to estimate the date and weight of the documents used, late forged Sagas being treated precisely as authentic early poems or contemporary histories.

The work has, in fact, no scientific value. It will amuse "the general reader," but it is unsuitable for serious students. To the archæologist it may serve as a rough index to the chief finds made in the three Scandinavian countries; but even for this purpose he will need to refer to the original plates and cuts from which the illustrations in these volumes are more or less happily reproduced. This will be obvious to anyone who studies the originals in the papers of Montelius, the Proceedings of the Stockholm Congress, 1874, the splendid Copenhagen Museum Catalogues, or the "Aarbøger for Nordisk Old-kyndighed og Historie." F. Y. P.

A Glossary of Anatomical, Physiological, and Biological Terms. By T. Dunman. Second Edition. Edited, and supplemented with an Appendix, by W. H. Wyatt Wingrave, M.R.C.S. (London: Griffith, Farran, Okeden, and Welsh.)

IT is now eleven years since the first edition of this book appeared. The senior author outlived its publication by but a short period. The editor of the present edition has left its pages unaltered, and has taken upon himself to add thereto (in the form of an appendix) twenty-five pages, embracing some 400 physiological and morphological terms, to the paucity of which, in the original edition, he directs attention. Many of his supplementary words are superfluous, others are obsolete, and by no means a few are either insufficiently or inaccurately explained. The original edition was by no means free of like defects: in it we read, by way of example, that the "*Sepiostaire*" is "the only representative of an endoskeleton in the cuttle-fishes"; that the "*Septum lucidum*" is "the partition which separates from each other the lateral ventricles of the brain"; that by "*Schizocœle*" is meant "a term applied to the peri-visceral cavity of the Invertebrata, when formed by a splitting of the mesoblast of the embryo." The present editor, while preserving the above and many other similar misstatements, has, in turn, shown himself wanting in power of accurate definition of fundamentals. This is seen, for example, in his renderings of "*Endomysium*," "*Inhibition*" (defined as "checking or controlling influence, exercised by a nerve-centre over some subordinate organ or process"), "*Metabolism*," "*Meckelian bar*," and *Negative variation*" (which, we are told, embraces "changes in the natural nerve or muscle currents which occur during contraction"). The little volume has hitherto recommended itself to students chiefly by its compactness. There has always characterized it a want of expressiveness and of finish. A single instance will suffice: "*Glomerulus*" has all along stood, and still stands, as "the small ball of capillaries in the Malpighian capsules of the kidney." It is the first duty of an editor of a new edition to rectify original defects; and, until that shall have been done, he has no right to add supplementary matter. The volume, as it now stands, must be speedily revised, if the recommendation of experienced teachers is to be looked for; and it is upon the same that it can alone maintain its honoured position.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Acquired Characters and Congenital Variation.

BEING one of those who do not believe that either the theory of Darwin or the theory of Lamarck gives any adequate or rational account of the "origin of species," I am always glad to see any controversy which pits the one of them against the other. It is by such controversy that the weak points of each are best exposed. But I now write in the interests of peace and conciliation. Prof. Ray Lankester seems to me to be much too belligerent. I see no necessary antagonism between "congenital variation" and the transmission of "acquired characters." If an acquired character affects the whole organism, and especially the reproductive elements, then its hereditary transmission would perfectly reconcile the two conceptions. And this is probably the universal fact. I have no doubt of the hereditary transmission of acquired characters. So far is it from being "unproved," it is consistent with all observation and all experience. It lies at the foundation of all organic development. But it implies the denial of "congenital" causes. It is very probable that every "acquired character" is necessarily correlated with some physical modifications in organic structure, and that it is only transmitted to progeny through, and by means of, this physical modification.

This being so, the question arises, Why is it that the idea of acquired characters becoming hereditary is so fiercely opposed by extreme Darwinians? Is it the mere jealousy of an exclusive worship—the mere dislike of the great name of Lamarck being mentioned, even in the same day, with the name of Darwin? It is partly this, no doubt. But it is something more. It is jealousy of any conception which tends to break down the empire of mere fortuity in the phenomena of variation. Darwin himself is not wholly responsible for this feeling. He expressly guarded himself against the interpretation which has been affixed to his language about "accidental" variation. He knew well

enough that variations must be governed by some law. But as we are absolutely ignorant what that law is, he thought it allowable to make provisional use of the word accidental. But the "neo-Darwinians" (as Prof. Ray Lankester calls them) are not content with this dethronement of their idol, Fortuity. The supreme and everlasting rule of pure accident is their creed and worship. Hence comes Prof. Ray Lankester's simile of the kaleidoscope, by which he illustrates the genesis of "new characters" in organic life. There is, he indicates, no more connection between those "new characters" and their origin in the parent, than there is between the new patterns which tumble in a kaleidoscope and the tap upon the tube which shakes them out.

There is no argument so false as a false analogy. And this is a case in point. Every illustration or analogy must be false which confounds mere mechanical arrangement with organic structure. They are not only different, but they are different in kind. Neither mechanical aggregation, nor mechanical segregation, can possibly account for the building up of organic structures. To attempt to account for such structures by causes similar to those which determine the arrangement of tumbling bits of glass, is even more irrational than it would be to account for the structure of a great cathedral by explaining to us how its bricks or its stones were made. There is one grand peculiarity in all organic structures which all such illustrations are framed to conceal. That grand peculiarity is this—that they are all made for work, for the discharge of some function. They are where they are not merely because somehow they have been put there. But they are what they are, and where they are, because they have some given work to do. But more than this: they all pass through stages of development in which their work cannot as yet be done. In all these stages, that work lies before them in respect to time, and behind them in respect to adaptation. They are all of the nature of an "apparatus." This is the word which the profound but unconscious metaphysic of human speech has invented for them. It is the word chosen by natural selection, and, as such, it ought to secure the homage even of Prof. Ray Lankester himself. The idea, however, comes before the word—shapes it, and inspires it—just as the needs of function, and the organic necessities imposed by inorganic laws, have shaped and inspired the growth and development of every organic apparatus.

I am very glad to see that under the stress of controversy the Professor admits—and even hotly denies that it has ever been doubted—that natural selection cannot account for the pre-existence of the structures which are presented for its choice. And not only must selected organs exist before they can be chosen by natural selection, but they must have been already sufficiently developed to possess some functional activity. This was my contention thirty years ago, and to this day I have always found it either denied or evaded by the whole ultra-Darwinian school. I rejoice to see it now admitted as unquestionable. "Natural selection can account for the origin of nothing"—so says Mr. Cope. The Professor indignantly replies: "How can Mr. Cope presume to tell us this? Who has ignored it? when? and where?" So ends a long and a hard fight. The enemy not only lays down his arms, but denies he has ever carried them. ARGYLL.

Who Discovered the Teeth in Ornithorhynchus?

IT is almost superfluous to add anything to Prof. Flower's reply (p. 151) to Dr. Hart Merriam. In justice, however, to Mr. Poulton, it ought, I think, to be stated that he fully refers to Home's paper in the Philosophical Transactions. In the *Quart. Journ. Micr. Sci.*, vol. xxix. p. 27 (a paper to which Dr. Hart Merriam alludes as though he had read it) Mr. Poulton, describing the horny plates of Ornithorhynchus, writes as follows: "Home (Phil. Trans., 1802, p. 71) correctly describes these horny plates as differing 'from common teeth very materially, having neither enamel nor bone, but being composed of a horny substance only embedded in the gum,'" &c. I observe too, with great interest, that in the same paper Home makes use of the expression (p. 70) "the teeth, *if they can be so called.*" On p. 28 Mr. Poulton quotes in full the passage from Owen given by Prof. Flower. Perhaps Dr. Hart Merriam does not accept Owen's correction of Home's hypothesis. It is hardly necessary to point out that the teeth which Mr. Poulton describes (p. 15 *et seq.*) under the headings (1) tooth papilla; (2) dentine; (3) enamel; (4) inner epithelium of enamel organ; (5) stratum intermedium of Hannover; (6) middle membrane of enamel organ; and (7) outer membrane of enamel organ, *must* be very different from those which Home calls "cuticular," and further qualifies as in the sentence which I have quoted.

Comparison of Home's figures with Mr. Oldfield Thomas's (Proc. Roy. Soc., vol. xlvi. pl. 2) renders it highly probable that the true teeth of Home's younger specimen had only recently dropped out from the horny plates; the dimensions given by the two authors being almost identical. But Home's description is perfectly definite, and no hint whatever is made to true teeth situated upon the horny plates such as those described and figured by Mr. Oldfield Thomas. The length of the skull of Home's specimen, as given in his figure, is 71 millimetres, while that of Thomas's female specimen is 65 millimetres; the male is slightly larger. Probably, therefore, Home's specimen was considerably older than Thomas's, and had lost the true teeth for some little time.

The only conclusion at which I can arrive is that Dr. Hart Merriam did not read any of the three papers bearing on this subject with sufficient care and attention to enable him to fully understand the facts ascertained by their respective authors, if indeed he proceeded further than the introductory remarks prefacing Mr. Oldfield Thomas's communication to the Royal Society. OSWALD H. LATTER.

Anatomical Department, Museum, Oxford, December 20.

Galls.

IN answer to Mr. Ainslie Hollis, I should like to observe that, in my opinion, the theory of natural selection is *not* "seriously assailed by investigations into the formation of galls by insects." On the contrary, in reply to what appeared to be a challenge from Mr. Mivart, I pointed out the manner in which natural selection might here be fairly supposed to have operated. But, while doing this, it appeared desirable to add that the case is a highly peculiar one. If galls were merely amorphous tumours, or even if they presented but as small an amount of specialization for the benefit of the larvæ as is presented by animal tissues for the benefit of their parasites, the case would not be so peculiar. But the degree of morphological specialization which the "pathological process" presents in the case of some galls—and this, of course, for the exclusive benefit of the contained parasites—is very remarkable. And although I doubt not that it is but a higher exhibition of the same principles as obtain in the case of animal tissues and their parasites, it is a case of much greater interest from the Darwinian point of view. For, if the explanation given in my last letter be accepted, the facts show how enormous must be the power of natural selection in building up adaptive structures, seeing that it can do this in so high a degree even when working, as it were, at the end of a long lever of the wrong kind—*i.e.* acting *indirectly* on the vegetable tissues through the benefits thereby conferred on their animal parasites. I am not aware that there is any other instance of "symbiosis" where so high a degree of adaptive specialization is presented by one of the "partners" for the exclusive benefit of the other. GEORGE J. ROMANES.

London, December 13.

MR. W. AINSLIE HOLLIS has involuntarily misrepresented me as saying that the theory of natural selection can be "seriously assailed" by investigations respecting galls. I said, indeed (NATURE, November 14, p. 41), that it would be "very interesting to learn how" natural selection could have caused them; but I was careful to add that doubtless an explanatory hypothesis was ready to hand. I do not myself believe they were so caused; but if they were not, they would none the less, like almost all biological phenomena, be explicable by an unlimited use of gratuitous hypotheses concerning physiological correlations and imaginary ancestors.

I confess I do not see that calling them "pathological" (an epithet I certainly would not deny them), and comparing them with inflammatory renal foci due to Bacilli, will explain them, unless it be affirmed that pathological conditions favourable to parasites are always due to the action of "natural selection" on the parasites themselves—an affirmation which appears to ask too much.

Herr Wetterhan's argument from *symbiosis* sins against natural selection itself. For that theory requires that, in the arduous and incessant struggle for life it supposes, any prejudicial growth should, in time, be eliminated unless carrying with it some preponderating advantage. The insect and the plant are

not "partners," for the latter does not participate in the gain of the former. How, then, on symbiotic principles, can "natural selection" have been the means of producing a growth which, though important, if not necessary, to the animal symbiont, is more or less prejudicial to the symbiont vegetable organism?

There can, of course, be no doubt, as Mr. McLachlan says, that the various peculiarities of gall-structure "could be" explained "on purely physiological grounds if carefully studied;" but that "natural selection" will suffice to explain them, seems to me by no means equally free from uncertainty.

St. George Mivart.

Hurstcote, Chilworth, December 13.

The Permanence of Continents and Oceans.

I can find no flaw in the reasoning on the dynamical question of the permanence of continents and oceans, in Mr. Starkie Gardner's letter in Nature of December 5 (p. 103), by which he endeavours to show the universal "tendency for deep oceans to become deeper, and for mountain chains to grow into higher peaks." But when he says it is opposed to no known facts, I wish to ask how it is to be reconciled with the fact of the general distribution of marine deposits over the face of the earth, so that every part of what is now land appears to have once been ocean?

I fully concede that the change of ocean spaces into land spaces is an extremely slow process, taking, probably, millions of years, but it seems to me that it must have occurred, though I cannot suggest through what agency.

Belfast, December 14. Joseph John Murphy.

Does the Bulk of Ocean Water Increase?

Mr. Jukes-Browne (Nature, December 12, p. 130) admits that "if the area of the land were larger, and the depth of the oceans less," in early geological times, a further inference must be drawn—"that the bulk of the ocean water was less then than it is now."

So far we are in agreement; indeed, we could scarcely be otherwise, as the proposition admits of complete demonstration. When, however, Mr. Jukes-Browne proceeds to give his reasons for holding that the bulk of ocean water *was* less in early times than now, he enters upon a more controversial subject.

I am familiar with the arguments he urges partly on the authority of Mr. Fisher, and have to some extent discussed them in chapter xii. of the "Origin of Mountain Ranges." I desire, however, to point out a further objection that when stated will, I think, appear extremely obvious.

According to Dr. George Darwin and many other astronomers who follow him, our satellite, the moon, was once an integral portion of the earth, having been thrown off when the earth was in a molten condition. If this theory be correct, it is a fair assumption that the magma out of which the moon has consolidated was composed of matter similar to that of our earth. Even if their relations were never so intimate as this, I think most physicists and astronomers will admit a similarity of material constitution of the two spheres.

If then volcanic action on the earth is, as Mr. Jukes-Browne contends, accompanied by a separation of water initially contained in the magma, and its condensation on the surface in such quantities as to materially increase the bulk of ocean water, why has not the same effect followed volcanic action on the moon? Why, in fact, do we not see oceans on the surface of the moon instead of a dry and desert waste of volcanic rings, mountain protuberances, and arid plains? In face of this great fact it appears to me that ingenious arguments as to the amount of water contained in the fluidal cavities of granite, which most geologists think is explicable by percolation, have not much weight.

At all events, it seems a reasonable question to ask why oceans should be supplied with water from the perspiring pores of mother earth, while her offspring, the moon, is so dry as to have absorbed into herself all evidence of any aqueous envelope that may have formerly existed. T. Mellard Reade.

Park Corner, Blundellsands, December 14.

A Natural Evidence of High Thermal Conductivity in Flints.

A rather curious effect of the recent frost attracted my attention in the gravel foot-paths leading over Addington Hill, near Croydon, on the beautifully bright day of the 1st inst. The clear nights and frosty air of the closing week of last month had been productive of continued low temperatures in that locality, and the result observed was that the flint pebbles, which in neighbouring gravel-beds and here and there on the paths, are of the size of hens' eggs, and remarkably well rounded, had, in places, sunk in the frozen clunch or clay-earth of the foot-paths, and in the peaty ground or turf beside the paths, as it appeared, like filberts shrunk and resting at the bottoms of their shells; or else as if the pebbles' earthy moulds had, by expanding upwards, left such a large vacuity above each stone, that the tops of some of the large ones, instead of being level (as at first they must have been, by the appearance of the moulds) with the surface of the ground, were now, in a somewhat turfy place, about as much as half an inch below it. The physical enigma which hereupon offered itself for elucidation was, how the pebbles could remain at the much lower level, while such a considerable expansion upwards had been brought about by freezing in the moist earth immediately surrounding them; and this problem had certainly, in looking at the thickly-clustered cavities in the frozen ground, at first a very paradoxical appearance.

But if the question how the inclosing cavities of moist earth round flint pebbles which are nearly embedded in it, are distended upwards so curiously by a strong frost's predominance, has presented, it may be, to some of your readers who may have noticed in similar conditions a similar appearance, as it at first did to me, a subject for rather puzzled contemplation and conjectures, it will be worth pointing out, perhaps, that there is a well-ascertained thermal property of siliceous rocks and flint, of which it seems not improbable that this not unfrequently occurring action of a strong frost, in such conditions, may really be an interesting illustration.

Among a series of about a hundred different descriptions and varieties of commonly occurring rocks whose thermal conductivities were experimentally determined by a Committee of the British Association in the years 1874–78, it was found that such entirely siliceous ones as quartz, flint, and pure siliceous sandstone, &c., so much surpass all other ordinary rocks in their rates of transmitting both heat and temperature, that in flint pebbles these conducting powers are, for example, about four or five times as great as in damp sandy mould, or in wet clayey earth.

Instead of the layers of cold temperature, therefore, produced in wet pebbly ground by continued frosty winds and radiation, proceeding in plane levels downwards from one depth below the surface to another, large flints exposed in it must grow cold very quickly through their whole substance, and must freeze the wet earth under them almost as soon as the soil's surface-layer round them is beginning to be frozen. The effect of this freezing process's expansion, it seems evident, will hardly be so much to raise the pebbles and the earth's exposed surface upwards very differently from each other, by the frost's nearly equal action on them both, as, during the frost's continuance, to force up towards the surface a large superfluity of soft earth from between the bedded stones, carrying the cast or mould of the stone's upper sides, itself to some height above them. We would require, perhaps, as an aid to this interpretation of the process, to regard the congelation round the stones, as rooting them down, perhaps to lower-lying ones, so that the upward thrust of the extruded earth may not be able to dislodge them, but can be effective to raise up their frozen caps; but some such supposition as this does not appear to be a very impossible conjecture. By this recourse to the pre-eminent thermal conductivity of flints above that of moist turf and clay, in which they are embedded, it seems at least not impracticable to give a somewhat intelligible explanation of the frozen ground's abnormal elevation round them, lifting the moulded caps of earth-covering off their upper sides until their roadside clusters present the curious appearance of shrunken petrifactions of some nest of fossil yolks in half-empty egg-shells.

It is, indeed, true that when by long continuance of a frost the sodden earth may have become entirely penetrated and frozen by it to some considerable and tolerably even depth (we may suppose) below a layer of embedded flints, it should be noticed, to simplify the process's consideration, that the form which the frozen ground will then have acquired between and round the flints could be nowise affected in the end by any various shapes, plane or contorted by irregularly formed and differently conducting solid bodies in its course, wherewith the tract of

reezing temperature after entering the ground approaches by stages of quick or slow rates, in different parts, towards the supposed nearly even depth at last, if we might only presuppose that, because of the endless material obstruction to its motion in any horizontal direction, no channels for the earth's lateral expansion in freezing should subsist; but that in all places and in all conditions where the freezing happens, the only line of escape of the earth's increase of volume should be vertically upwards towards a direction where no insuperable forces are, at least, opposed to it.

Were this assumption of upward reliefs only of all of the expansions a really true and valid one, every vertical fibre of the wet earth's mass would behave in freezing quite independently of every other one, and would take up its fully expanded length at last, no matter at what times and in what order congealing overtook its individual portions. A stone, in this supposition, just embedded in the ground, would have its lower half lifted at last in its socket, and the upper half of the socket lifted off the stone (whether its thermal conductivity is great or small), to the height, in either case, of a water-column's change of length by freezing, whose initial height is but half the vertically measured thickness of the round embedded stone—that is to say, about one-eleventh of an inch for a stone 2 inches in diameter, instead of nearly half an inch, which was about the depth of the settlement, in some of the large-sized flint stones, which was actually observed.

To return to the reality, however, from this artificial supposition, the actual course of the expansions, and the effects produced by the freezing dilatations must, no doubt, be very different. Supposing that the flint-stones, by their good thermal conductivities, soon become covered with a thickening coat of frozen earth, flow of the soft, unfrozen earth between them will really spring up and be maintained by direct outward expansions from the stones of the icy coats surrounding them. On account of the firm rigidity of the exposed earth-surface, to which the stones themselves must soon become fast fixed, the remnant flow of soft earth from between the stones, instead of finding an upward path the easiest, will rather choose a vertically downward one for its escape from its confinement, and lift the stones and icy covering together, rather than seek by an upward course to break through the latter. Yet this last effect may also perhaps occur to some extent, raising the frozen earth-caps in some measure off the stones' upper sides, and stretching them, it may be, a little upwards, so as to leave between them and the stones clear empty spaces. That this last effect must be only a secondary and inconspicuous one, however, seems to be pretty obvious from this passingly essayed, and as it now appears all too uselessly pursued and desultory *aperçu* of the frost's real mode and process of expansive action.

Regarding the peculiar structures, in fact, altogether from another point of view, and rejecting the imperfect explanation which any one of these presumed congelation processes might at first have been supposed to furnish, of the curiously sunken-looking assemblages of the wayside pebbles, an exactly opposite interpretation of their semi-interred condition seems, perhaps, indeed, to afford a more satisfactory and likely explanation of it, than the expansive effects of frost in the moist earth were ascertained and shown to have any capabilities and physical resources for. The warmth of the sun, or of wind and rain in some thawing daytime temperature of the generally frosty week, may in short be supposed (which the weather-table of the week, on the 26th and 27th ult. confirms) quite plainly and certainly enough, in consequence of the flints' good thermal conductivities, to have melted and shrunk again to its natural dimensions the hard frozen earth under them, without lowering the level equally of the badly conducting frozen earth surrounding them. Alternate days of thaw and nights of frost would, by progressive stages which can be easily traced out and understood, tend quite naturally to exaggerate this difference. Thus in another way, but complementary to and at returning times just fitly supplemented by that first supposed, the problem which the winter scene presented is, still more simply and clearly than before, seen to be solved quite truly and correctly by the relatively high thermal conductivity of the rounded flints as compared with that of the hard frozen earth in which they are enveloped.

This gradual subsidence, therefore, of flint stones during alternate frosts and thaws, into frozen earth, by consolidation and lateral expansion, followed by liquefaction and vertical contraction of the water in the earth beneath them, is, it would seem that we may reckon it accordingly, a phenomenon on land just analogous and similar to the familiar thermal process which small stones scattered on a smooth frozen glacier-field display in summer-time, by intercepting the heat of the sun's rays, and by sinking to the bottom of the deep water-holes which they thus scoop and delve out for themselves, wherever they happen to have found a lodgment in the naked ice.

A. S. HERSCHEL.

Observatory House, Slough, December 9.

Foreign Substances attached to Crabs.

AT the last meeting of the Linnean Society I exhibited a number of crabs and certain shells of the genus Phorus having various foreign substances attached to them, about which it is desirable that more should be known. Some of the crabs manage to fasten bits of sea-weed to the hairs on the carapace and legs; Polyzoa, Balani, Serpulæ, &c., in their earlier stages fasten themselves on others; a crab of the Indian Seas—*Camposcia retusa*—is sometimes completely covered on every part with sand, small shells, and bits of sea-weed—Corallina chiefly. These could only be attached by some adhesive matter, but whence derived? *Dromia vulgaris* is occasionally found with a sponge extending over the carapace and almost completely hiding the animal. The species of this genus have the two hinder pairs of legs much reduced, flattened, and lying close to the back, and this is assumed to be an adaptation for the purpose of retaining the sponge. Out of a number of specimens dredged in the Bay of Naples, I recollect only getting one with a sponge on it, and that very soon shrivelled up, leaving a leathery-looking substance attached to the base of the carapace, not held by the legs apparently.[1] Two crabs—*Æthusa mascarone* and *Dorippe lanata*—having similarly reduced hind-legs, but directed upwards, seem much better adapted for retaining a foreign substance, which, however, they are not known to do. In a Mauritian crab—*Dynomene hispida*—the hind pair only are reduced, but to such an extent as to be merely rudimentary and incapable of any use. *Paramithrax barbutus*—a New Zealand crab—has, like some others, hooked hairs, but in the specimen exhibited they appear to be free of any foreign substances, although many small fragments of an uncertain nature appear between them.

In Phorus a strong cement only could hold on those large and heavy substances—shells, stones, &c.—completely covering the shell, as in *P. agglutinans*. I have not seen any account of their *modus operandi*, but, as the animals have a long proboscis, it is possible that that may be the organ employed, but it is difficult to believe that it would be able to lift any large substance, or that it could reach the top of the shell. Another difficulty is that they must cast off, from time to time as they grow, the smaller substances, to replace them by larger ones. There is one Phorus, however—*P. calyculatus*—in which small shells imbed themselves at short intervals along the whorls, leaving the greater part of the shell uncovered; these little cup-shaped depressions are marked inside, as far as the mouth of the shell will permit them to be seen, by corresponding protuberances. This would seem to indicate a certain softening of the shell at one time or other.

I do not see where protection comes in, in any of these cases.

December 14. FRANCIS P. PASCOE.

[1] Bell, in his "British Crustacea" (p. 371), states having received "numerous young specimens from Sicily, every one of which had the carapace entirely covered with a sponge, which had grown over it, concealing even the two hinder pairs of legs, which were closely placed against the back, and rendered immovable." No mention is made of a sponge on those that came from the Channel.

A Marine Millipede.

IN the hopes of arousing the interest and the energies of British entomological collectors, "D. W. T.," in a short notice on p. 104 of the present volume of NATURE, draws attention to the recent discovery in Jersey, by Mr. Sinel, of that remarkable marine centipede *Geophilus* (*Schendyla*) *submarinus* (not *submaritimus* by the way), of Grube.

Those who observed this notice, and are interested in the fauna of Great Britain, may be glad to hear in addition that more than twenty years ago a number of specimens of this then undescribed species were taken by Mr. Laughrin at Polperro on the south coast of Cornwall. These specimens, which were presented to the British Museum in 1868, were found associated with *Linotænia maritima* (Leach)—also a marine centipede—

among the rocks on the sea-shore; but whether the place of their capture was above or below high-water mark, is not stated on the ticket with which the specimens are labelled.

Dr. Grube's specimens were taken at St. Malo.

December 17. R. I. POCOCK.

SUGGESTIONS FOR THE FORMATION AND ARRANGEMENT OF A MUSEUM OF NATURAL HISTORY IN CONNECTION WITH A PUBLIC SCHOOL.

HAVING lately been asked by Dr. Warre, Head Master of Eton, to give him some assistance in the fitting up, arrangement, and management of the museum about to be inaugurated at that College, I put down some notes, which he was pleased to think might be of use in pointing out the lines that should be followed with most advantage. As these notes are equally applicable to other school museums, I venture to publish them for the information of those who may be in position to profit by them, premising that they are mere outlines, which are susceptible of much elaboration in detail, and of some modifications according to special circumstances.

The subjects best adapted for such a museum are zoology, botany, mineralogy, and geology.

Everything in the museum should have some distinct object, coming under one or other of the above subjects, and under one or other of the series defined below, *and everything else should be rigorously excluded.* The curator's business will be quite as much to keep useless specimens out of the museum, as to acquire those that are useful.

The two series or categories under which the admissible specimens should come are the following:—(1) Specimens illustrating the teaching of the natural history subjects adopted in the school, arranged in the order in which the subjects are, or ought to be, taught. (2) Some special sets of specimens of a nature to attract boys to the study of such branches of natural history as readily lie in the path of their ordinary life, especially their school life, and to teach them some of the common objects they see around them.

The specimens of the first class should be all good of their kind, carefully prepared and displayed, and fully labelled. They should also be so arranged that they can be seen and studied without being removed from their position in the case or in any way disturbed or damaged. It would be best that they should never be taken out of the museum, but if it is necessary to remove them for the purpose of demonstration at lectures or classes, special provision should be made by which a whole tray or case can be moved together, with due precautions against disturbing the individual specimens. As a rule, the teachers should either bring the classes into the museum for demonstrations, or they should rely upon a different set of specimens kept in store in the class-rooms, and only brought out when required, and which may be handled and examined without fear of injury. Really good permanent preparations may be looked at, but not touched except by very skilled hands.

In zoology the collection should consist of illustrations of the principal modifications of animal forms, living and extinct, a few selected typical examples of each being given, showing the anatomy and development as well as the external form. The series now in the course of arrangement in the Central Hall of the Natural History branch of the British Museum, in the Cromwell Road, may, as far as it is complete, be taken as a guide, but for a school museum it will not be necessary to enter so fully into detail as in that series.

In botany there should be a general morphological collection, showing the main modifications of the different organs in the greater groups into which the vegetable kingdom is divided, and illustrating the terms used in describing these modifications. Such a collection may also be seen (although still far from complete) in the same institution.

For a teaching collection of minerals, an admirable model has for several years past been exhibited in the Mineralogical Gallery of the Natural History Museum, being, in fact, the various paragraphs of Mr. Fletcher's "Introduction to the Study of Minerals" cut up, and with the statements in each illustrated by a choice specimen.

The geological collection would best be limited mainly to a series illustrating the rocks and characteristic fossils of the British Isles, arranged stratigraphically. There would be no difficulty in making such a series on any scale, according to the space available, and if well selected and arranged, it would be extremely instructive and form a complete epitome of the whole subject. It should be placed in a continuous series along one side of the room, beginning with the oldest and ending with the most recent formations. It might be preceded by some general specimens illustrating the various kinds of rock structures, &c.

Mineral and fossil specimens are generally to be procured as wanted from the dealers, and as they require little or no preparation, collections illustrating these subjects can be quickly made, if money is available for the purpose. This is not, however, the case with zoological and botanical specimens, most of which require labour, skill, and knowledge to be expended upon their preparation before they can be preserved in such a manner as to make them available for permanent instruction.

We will next proceed to consider what objects may be included under the second head, many of which need not be constantly exhibited, but may be preserved in drawers for special study. These may be—

(1) A well-named collection of the commoner British insects, especially those of the neighbourhood in which the school is situated, with their larvæ, which should (if means will allow) be mounted on models of the plants upon which they feed. All should have their localities and the date of capture carefully recorded. These are best kept in a cabinet, with glass-topped drawers, with a stop behind, so as to allow them to be pulled out for inspection, but not entirely removed. Such a collection, formed of specimens prepared and presented by Lord Walsingham, can now be seen in the British Room of the Natural History Museum.

(2) A similar collection of British shells, especially the land and freshwater shells of the neighbourhood.

(3) If space and means allow, a collection of British birds, especially the best-known and more interesting species. Rare and occasional visitors, reckoned in the books as British, which are the most expensive and difficult to procure, are the least important for such a collection. Variations in plumage in young and old, and at different seasons, should be shown in some common species. Every specimen must be good and well mounted, or it is not worth placing in the museum.

(4) The principal British mammals of smaller size, especially the bats, shrews, and mice.

(5) The British reptiles, Amphibia, and commoner fishes, so shown that their distinctive characters may be recognized.

(6) A collection, as complete as may be, of British plants, or at all events of the plants of the neighbourhood. By far the best way of preserving and exhibiting such a collection is in glazed frames, movably hinged upon an upright stand, as may be seen in the Botanical Gallery of the Natural History Museum. A collection arranged in this manner should find a place in every local museum of natural history.

(7) A collection of the fossils found in the quarries of the neighbourhood, should there be any.

Every collection or series should be kept perfectly dis-

tinct from and independent of the others, and its nature and object clearly indicated by a conspicuous label.

The exhibited specimens should be arranged in upright wall-cases or in table-cases on the floor of the room. For the latter a high slope is preferable, and in all the exhibition space should not extend too high or too low for comfortable inspection. Between three to six or seven feet from the floor should be the limits for the exhibition of small objects. The three feet nearest the floor may be inclosed with wooden doors forming cupboards or fitted with drawers. Glass in this situation is liable to be broken by the feet or knees.

The museum should have a permanent curator—a man of general scientific attainments, and who is specially acquainted with, and devoted to, museum work, and who might also be one of the teachers, if too much of his time is not so occupied. But, as he is not likely to have special knowledge of more than one branch of natural history, the teachers of the other branches represented in the museum would probably each give advice and assistance with regard to his own department. It is also probable that some of the boys may be sufficiently interested in the work to render valuable aid in collecting and preparing specimens.

If ethnographical, archæological, historical, or art collections be also part of the general museum scheme, they should be kept quite distinct from the natural history collections, preferably in another room.

Above all things, let the following words of Agassiz be remembered: "The value of a museum does not consist so much in the number as in the order and arrangement of the specimens contained in it."

W. H. FLOWER.

THE FISHERY INDUSTRIES OF THE UNITED STATES.

THE volumes which form the subject of the present article are the continuation of a complete monograph of the fisheries and fishing industries of the United States, of which the first and second sections have already been published under the titles of "A Natural History of Useful Aquatic Animals," and "A Geographical Review of the Fisheries of the United States."

The direction of the immense investigation necessary for the preparation of this work has been in the hands of Mr. G. Brown Goode, who, as early as 1877, had drawn up a scheme for an exhaustive exploration of the coast of the United States in connection with the fishing industry. The enterprise was undertaken jointly by the United States Fish Commission and the Census Bureau, and the expenses of investigation, compilation, office and field work, and publication, have been shared by these two departments.

A work of this magnitude was quite beyond the powers of an individual, and we find accordingly that a number of authors, whose names are given at the back of the title-page, have been associated with Mr. Brown Goode in his undertaking. Among them are many names well known to science from their contributions to the natural history of the United States. Chief among these are Messrs. Marshall MacDonald, J. A. Ryder, and other members of the United States Fish Commission.

An English reader will invariably use his knowledge of British fisheries as a standard for comparison with those of a foreign country, and, in doing so, will find many difficulties, owing, not only to the difference in the species of fish which are found on the two sides of the Atlantic, but to the fact that many of our common names, such as pollack and hake, are applied to different fish in America, and that the Americans often use an altogether peculiar zoological nomenclature, which may throw even an experienced zoologist into confusion. Many American fishes of great commercial importance are unknown in Great Britain, such as the tautog (*Tautoga onitis*), the squeteague (*Cynoscion regale*), the blue-fish (*Pomatomus saltator*), the menhaden (*Brevoortia tyrannus*), and the shad (*Clupea sapidissima*). The most favourite edible crab of North America (*Callinectes hastatus*), the blue crab, is a perfectly distinct species from our common *Cancer pagurus*, and the American lobster (*Homarus americanus*) and oyster (*Ostræa virginica*) are different from our own. The European sole is unknown in American waters, as are our turbot and brill; the halibut, which has only recently become important in British fisheries, is of great importance in America, and their "plaice" (*Paralichthys dentatus*) differs entirely from the fish known to us by that name. These and many other differences in the species of marketable fish are important, as they serve in part to explain the different methods pursued by American fishermen; why, for instance, beam-trawling is unknown in their waters.

Of the third section of the monograph, which forms a half of the first of the four volumes under consideration, Mr. Brown Goode himself says:—"It is the first report of the kind ever written. It describes the locations, the characteristics, and the productiveness of the numerous grounds resorted to by the fishermen of the United States, extending from Greenland to Mexico, from Lower California to Alaska, and including the fishing grounds of the great lakes." For the Atlantic seaboard this work is carried out on a scale of completeness never before attempted. Not only does the text abound with information relative to the different fishing grounds and banks, their history, productiveness, the character of their bottom, and the weather prevailing there at different seasons, but the whole of this is graphically represented in a series of admirable charts which form in themselves a complete fisherman's guide to the whole coast from Greenland to Mexico. In addition to this, the migrations of different species of fish from locality to locality are alluded to, and the characters of the invertebrate fauna are, in some instances, adduced in explanation of these migrations. It is impossible to criticize this part of the work: to do so one must have a thorough knowledge of all the principal fishing-grounds of America; but, granted that the information and observations on which the charts and text are founded are correct, the method of displaying this information is unimpeachable.

Not the least valuable part of Section III. is the appendix containing the temperature observations from 1881 to 1885 inclusive. A word as to the manner of making these observations will not be out of place. The Census Bureau was, of course, unable to undertake this kind of work, and the Fish Commissioners, whose steamers were constantly engaged in expeditions to various localities, found that they could not keep a sufficiently continuous record of the temperatures observed at different points along the coast. Application was accordingly made to the United States Lighthouse Board and Signal Service, and these departments instructed their *employés* to make the required observations as part of their regular duties, and without extra compensation. The editor acknowledges the thoroughness with which these men performed the gratuitous services demanded of them, and the result is a large number of charts of temperature curves for each observing station, and charts showing the isothermal lines connecting the stations in different years.

The Pacific fisheries are dealt with in a much less complete manner, and are referred to as being undeveloped. The Alaskan fisheries are more fully dealt

[1] "The Fisheries and Fishery Industries of the United States." By George Brown Goode, Assistant Secretary of the Smithsonian Institute, and a staff of Associates. Section III. The Fishing-Grounds of North America, with 49 Charts, edited by Richard Rathbun. Section IV. The Fishermen of the United States, by George Brown Goode and Joseph W. Collins. Section V. History and Methods of the Fisheries; in Two Volumes, with an Atlas of 255 Plates. (Washington: Government Printing Office, 1887.)

with, and have a special interest as forming the chief, if not the only means of subsistence of the native population. The methods of fishing adopted there are of the most primitive character, and very few civilized fishermen are employed in the industry. Fish, however, is exceedingly abundant, and its value is shown by the price of salmon (*Onchorhynchus*) in the Yukon River. Dried salmon is called *ukali*, and the best quality *chowichee ukali*. One *chowichee ukali* is accounted a sufficient day's food for six men or dogs, and can be purchased for one leaf of tobacco, or five to eight musket-balls.

The fourth section of the monograph relates to the United States fishermen themselves. In 1880 there were 101,684 *bonâ fide* professional fishermen in the United States, those men only being reckoned as fishermen who make more than half their income by fishing. At the same time there were in Great Britain and Ireland between 90,000 and 100,000 fishermen who would come under this definition. It appears that whalers and sealers are reckoned among the American fishermen, and as they are certainly not reckoned in the English computation, the number of men engaged in fishing, properly so called, would be about equal in the two countries. Of the United States fishermen, the majority, including the negroes of the Southern States, and the Alaskans, are native-born American citzens, while from 10 to 12 per cent. are foreigners. The majority of the latter are natives of British provinces; the remainder are made up of Portuguese from the Azores, Scandinavians, Irish, and Englishmen, Italians, Indians, and, on the Pacific coast, Chinese. The chapters devoted to the fishermen of the different States are very interesting. The description of the Maine fishermen might be taken from any English fishing port. They are hardy, self-reliant, and honest, but are ill educated, inveterate grumblers, and entirely in the hands of the middleman. They will work hard when fishing, but are reluctant to undertake any other work, even for good pay. They marry early, and have large families, whilst their profits are low, the average annual return to each fisherman being $175 (about £36).

Oyster-dredging seems to have a peculiarly demoralizing effect in the United States, the white oystermen of Maryland being reckoned as the lowest of their class. The New England fishermen are the best educated, the most enterprising, and the most successful in the United States. Unlike the majority of European fishermen, they do not form a class apart, and have no peculiar traits or characteristics marking them off from their fellow-countrymen. They are good men of business, and many of them have left the fishing trade altogether, and been highly successful in other branches of business. Their fishing-craft, nearly all schooner-rigged, are the finest and largest in the world, and their life on board is far more civilized and comfortable than anything met with in Europe. Their earnings are far higher than those of the Maine fishermen. A Gloucester man will commonly make $1000 (more than £200) in a year, whilst skippers who are partly owners have on rare occasions made as much as $10,000 to $15,000 in a single year (from £2000 to £3000). Men living under such conditions are naturally of a high standard of intelligence, and the U.S. Fish Commission have profited largely from the co-operation of the New England fishermen. They have from the first recognized the value of a scientific inquiry in fishing matters; have in many instances devoted themselves heartily to assisting the labours of the Commissioners; have kept regular records of their journeys, including observations on tides, temperatures, weather, and sea-bottoms; have collected the fauna of the different fishing-grounds, and otherwise have been instrumental in helping scientific observation. They have one and all been ready to profit by the information gained by the Commission, and have readily tried and adopted novel methods of fishing, such as gill-nets for cod-fishery, and purse-seines for catching mackerel.

It is obvious, from a perusal of this volume, that the American fishermen are far more careful of their fish than Englishmen; they do not thump them down on the deck and stamp about on them, as is too commonly done on a British smack; they carefully clean them on board, and store them in proper receptacles, and, where fish is cured, it is commonly done on board when the fish is perfectly fresh. The reputation of the Gloucester, Mass., fishermen is curiously illustrated by a petition sent to the Lord-Lieutenant of Ireland this year. It was reported that several American schooners were coming to fish for mackerel off the coast of Ireland, and the fishermen, who do not fear the competition of English and French boats, were in great alarm lest the Americans with their purse-seines and large boats should utterly sweep the seas of fish.

Section IV. closes with a description of the dangers to which American fishermen are exposed, and an account of the management of fishing-craft. The whole is most interesting reading.

Section V. comprises two thick volumes of text and one of plates. The subjects it deals with range from whale-fishing to sponge-gathering, from baiting hooks to preparing sardines. Each branch of the fishing industry is minutely described in the text; the history of the fishery is given; old and new methods are compared; the boats, crews, fishing-gear, methods of packing and curing on board are carefully explained, and the descriptions are supplemented by a profuse number of illustrations.

It will be unnecessary to follow the various branches of fishing in detail, but a few remarks on special forms of fishing will be of interest. As has been said above, the Americans have no beam-trawl fishery: the flat-fish which are so highly prized in Europe are either absent from the American shores, or are held in low estimation, and we find no special mention of flat-fish fisheries in this section, with the exception of the extensive fishery for halibut. There appears to be a prejudice against flat-fish in many parts of America, and there is certainly a prejudice against the use of the beam-trawl. If the latter were introduced, and the several flat-fishes which are abundant in some parts of the United States waters were thrown freely into the market, an important branch of fishery would no doubt be established. Halibut are caught in deep water by means of long lines, known in America as "trawls," just as they are by the Grimsby boats working in the neighbourhood of the Faroe Islands. The method of setting several long lines round the schooner by means of smaller boats called "dories," is well worth noticing, but the great risk to life entailed by the use of the "dories" is an objection to introducing this mode of fishing into British waters.

The cod-fishery of the United States is very large, and is carried on to a large extent on the Great Bank of Newfoundland, as well as on the Labrador and St. Lawrence coasts. There appears to be a fine cod-fishery off Alaska, but it has only been partially worked by a small fleet hailing from San Francisco. The cod-fishery was formerly, and still is to a large extent, carried on by hand lines and long lines, or "trawls," but in 1880 the U.S. Fish Commission succeeded in introducing gill-nets, long since used by the Norwegians, among the fishermen of Gloucester. The obvious advantages of the cod gill-nets are that they save the fishermen the trouble and expense of obtaining bait, which is often as difficult to procure as it is in England, and thus increase their profit; they are easily set and worked, they catch more than the long lines working on the same ground, and as the size of the mesh is adapted only for cod of a certain size, the small fish or "trash" pass through and escape. This is a good example of the practical usefulness of the U.S. Fish Commission.

The accounts of the menhaden and mackerel fishing show that the Americans are as prone to complain of particular modes of fishing as English fishermen: the purse-seine is as obnoxious to some of them as the beam-trawl is in England, and the use of steam is at least equally unpopular. Steam is used chiefly in the menhaden fishery, and this, in combination with the purse-seine, a net practically unknown in England, has, it is alleged, utterly destroyed the menhaden fishing in certain districts. This led to petitions to Congress for the protection of the menhaden fishery, and in 1882 and 1883 the matter was inquired into, and protective legislation recommended. The evidence of actual decrease in the fishery does not appear in the Report on the fishery, but as the Commissioner of Fisheries was a member of the Committee which drew up the Report recommending legislative interference, it is to be presumed that he was satisfied that the fact of a diminution of the menhaden, due to over-fishing, was established.

Mackerel-fishing is conducted entirely by sailing-boats, most of them schooners of sixty tons register and upwards, and in these days it is carried on almost entirely by means of the purse-seine. In England, the summer fishing for mackerel is carried on by means of hand lines, and small boats may be seen "railing" or "whiffing" amongst the schools of mackerel. This method was formerly followed in America, but is now, to all intents and purposes, a thing of the past, the figures of small boats "jigging" and "drailing," as it is called in America, being given only in illustration of an obsolete industry.

The purse-seine first came into general use in 1850, but its greatest development dates only from 1870, and since the latter date there has been great opposition to its use, on the score of its destructiveness. The statistics of the mackerel-fishery do not, however, warrant this opposition. Mackerel-fishing has always been uncertain, and, as early as 1660, prohibitory laws of various kinds were passed to prevent, as it was supposed, the destruction of this industry. In 1838, twelve years before the introduction of purse-seines, the catch of mackerel was very small, and then the blame was laid on "the barbarous method of taking mackerel called gigging." The largest take of mackerel in a single year was in 1831, when 449,950 barrels of pickled mackerel were officially inspected; the second largest catch was in 1881, when 391,657 barrels were inspected. The worst catch was in 1877, when 127,898 barrels were inspected. A glance at the official tables shows that the fluctuations in the mackerel-fishery are quite independent of the usual method of fishing. The use of purse-seines might advantageously be tried in England, though it was found a failure by American schooners fishing off the Norwegian coasts, because, as it was alleged, the mackerel moved there in smaller schools than on the opposite side of the Atlantic.

In the second volume, on history and methods, English readers will find especial interest in the account of the great fur-seal industry of Alaska, which is regulated, as is well known, by a wise law prohibiting the destruction of more than a fixed number of seals every year.

No one who reads these volumes can fail to be struck with the practical national benefit of the United States Fish Commission. The production of this great work is only a small part of their active usefulness, but if it be judged by its utility alone, it is an exceedingly important part. When finished, this monograph of the fishing industry of the United States will form a complete text-book of American fisheries in all their branches, and will serve not only to interest the American public in a great national industry, but as a reliable guide to all those who are engaged in the fishing trade itself. In many cases it will be eminently serviceable as a book of reference to the practical fisherman, informing him of the localities and characteristics of fishing-grounds with which he is unacquainted, of the kinds and abundance of fish that he may expect there at different seasons, and of the best methods of prosecuting fisheries to which he is unaccustomed. Capitalists and manufacturers will learn from it how they may most profitably embark in a new industry, and the consumer will know from it how to judge of the quality of the article he consumes, and where to obtain it to the best advantage. It is impossible to refrain from drawing a comparison between this enlightened support given to an industry which from its very nature is incapable of being benefited by private effort, and the comparatively small support given by the English Government to our own fisheries, which, when the whale and seal fisheries are discounted, are at least of equal value with those of the United States. There are, indeed, signs that it is being generally recognized that the *laissez faire* policy as applied to national fisheries is a mistake. It is to be hoped that, when our Government takes another step forward, the example of the United States may not be lost sight of, and that, in addition to a central office with its necessary clerks and official administrators, a staff of skilled scientific investigators and practical men may be appointed, such as will be able to produce as exhaustive a work as that under review.

NOTES.

On Friday evening last, Sir Lyon Playfair, having distributed the prizes and certificates gained by the students of the City of London College, delivered an interesting address, taking as his chief subject the need for vital improvements in English methods of education. There had been, he said, a marked change going on over the world in regard to work. Machinery had been taking the place of muscular labour. Less human labour was employed, but it was much better paid than formerly. The workman must adapt himself by trained intelligence to these changes, otherwise he would go to swell the ranks of unskilled labour. Foreign countries had been quicker awake to the changes that were going on than we had been. We were proposing technical education, while France, Germany, Belgium, and Switzerland had been adapting themselves to the altered state of things by improved schools, secondary schools, commercial, building, and other special schools, which they had been promoting for many years. Germans and Frenchmen were taking places in English counting-houses, because the youth of London had not been educated in those languages which were necessary to commerce. We were now beginning to awake to the necessity of doing what was being done in other countries. Until comparatively lately we had nothing but classical schools. The learned classes had been entirely separated from the people; but the people's knowledge of trade improved science, and science improved trade. The learned classes were ignorant of this. This was not the way that the magnificent science and literature of Greece and Rome arose. Their great philosophers were busy in commerce, and were acquiring experience and knowledge among the masses of their own countrymen. This, he was rejoiced to see, was what we were now trying to bring about in this country.

The formation of two new Microscopical Societies has recently been announced. One of these is the Scottish Microscopical Society, meeting in Edinburgh, with the following office-bearers: President, Prof. Sir W. Turner; Vice-Presidents, Prof. Hamilton and Mr. Ad. Schulze; Secretaries, Dr. A. Edington and Mr. Geo. Brook. This Society has already held two successful meetings. The other Society is the Italian Microscopical Society, intended to bring together microscopists from the whole of Italy. The subjects for research, specially mentioned in the prospectus, are animal and vegetable histology, petrology, bacteriology, and the structure of the microscope and its appliances.

At Leyden there is a fine ethnographical collection, which is especially valuable so far as it relates to the Dutch East Indian

territories. At present this collection is seen to great disadvantage, but there is some prospect that it may soon be transferred to better quarters. A Parliamentary Committee has recommended that proposals should be submitted to Parliament for the erection of a suitable building.

The Public Free Libraries Committee of Manchester, in their annual report, just issued, state that the success which has so long attended the working of the public free libraries in that city still continues in all departments. During the last twelve months the number of readers and borrowers at the various libraries and reading rooms (*i.e.*, the number of visits they made) reached an aggregate of nearly four millions and a half (4,442,499), being over 70,000 in excess of the previous year. The number of books used for home reading and for perusal in the reading rooms was 1,649,741. In the preceding year the number was 1,606,874, the increase being 42,867. The daily average of volumes used in all the libraries was 4700. Of the volumes issued to readers at the libraries, 336,058 were read in the reference library, 507,964 in the reading rooms attached to the branches, and 64,770 in the Bradford, Harpurhey, and Hyde Road reading rooms. The number of volumes lent out for home reading was 740,949. Out of these only sixteen are missing. There are now 197,947 volumes in the libraries. The committee express regret that the limited resources at their disposal prevent the extension of branch libraries and public reading rooms, but they trust that the Council will, before long, enable them to take the necessary measures for giving effect to the resolution of the Council passed unanimously on December 21, 1887, with regard to obtaining parliamentary powers for the removal of the present restriction of the rate (a 1*d.* in the £) to be expended for library purposes.

The following scientific lectures will probably be delivered at the Friday evening meetings of the Royal Institution before Easter, 1890:—January 24, Prof. Dewar, F.R.S., scientific work of Joule; January 31, Sir Frederick Abel, F.R.S., smokeless explosives; February 14, Prof. J. A. Fleming, problems in the physics of an electric lamp; February 21, Shelford Bidwell, F.R.S., magnetic phenomena; February 28, Prof. C. Hubert H. Parry, evolution in music; March 7, Francis Gotch, Esq., electrical relations of the brain and spinal cord; March 14, Prof. T. E. Thorpe, F.R.S., the glow of phosphorus; March 21, Prof. G. F. Fitzgerald, F.R.S., electromagnetic radiation. On Friday, March 28, a lecture will be given by Lord Rayleigh, F.R.S.

On December 8, at 6.30 a.m., a severe shock of earthquake was felt in Upper and Central Italy, Dalmatia, the Herzegovina, and Bosnia. At Serajewo three shocks were felt, the direction being from south-east to north-west. They lasted for five seconds each.

The inhabitants of the town of Reggio d'Emilia, in Upper Italy, are very much alarmed by the activity of the volcano, the Queccia de Salsa, which is situated about eight kilometres from the town. During the last two or three weeks it has thrown up lava, stones, and ashes.

In the *Comptes rendus* of the French Academy of Sciences for December 9, M. Angot has published an interesting paper on the observations of temperature at the top of the Eiffel Tower. The mean monthly maxima and minima for July to November inclusive are compared with those recorded at the Parc Saint-Maur. According to the usual decrease of temperature with height, the tower observations should be about 2°·9 lower than at the ground station, but the difference is much greater in summer during the day, and much less in winter during the night. In calm and clear nights especially, the temperature has been found to be nearly 11° higher at the summit than at the base. At the time of a change of atmospheric conditions, the change is manifested some hours, or even days, at the higher station. A striking instance of this occurred in November. After a period of high pressure, with calms and easterly breezes, the wind on the surface became strong, and shifted to south-south-west, and temperature rose. But the change had manifested itself on the tower on the evening of the 21st, and during the whole period from the evening of the 21st to the morning of the 24th, the temperature at the tower was higher than at the base, at some times even exceeding 18°. Observations made by a "swinging" thermometer at 11h. a.m. on the 22nd showed that the inferior limit of the warm current was approximately between 500 and 600 feet above the ground.

The Third Report of the Meteorological Institute of Roumania for the year 1888 shows that much progress is being made, with very scanty means, thanks to the willingness of the observers and to the voluntary assistance rendered in the preparation of the observations for publication. The Institute has been established only four years, and at the beginning of 1889 it numbered 21 stations of various classes, in addition to 42 rainfall stations. The observations are regularly published in the *Annales* of the Institute, a quarto volume of about 600 pages, about half of the volume being devoted to discussions, in French and Roumanian.

For a year past Mr. R. W. Schufeldt has been working at a memoir on the morphology and life-history of *Heloderma suspectum*, the well-known poisonous lizard of the south-western part of the United States. This memoir is now nearly ready for publication. Biologists have hitherto denied *Heloderma* even the rudiment of a zygomatic arch, and Dr. Günther, of the British Museum, has said in his article "Reptiles," in the ninth edition of the "Encyclopædia Britannica" (p. 451), that "the skull of *Heloderma* is very remarkable in that it has no zygomatic arch whatever." We learn from Mr. Schufeldt that his recent dissections of this lizard go to prove that such statements must be qualified. Upon examining skulls of both old and young individuals of *H. suspectum*, he has found at least a very substantial vestige of the arch in question. It consists of a freely articulated, conical ossicle, standing on the top of the quadrate, being moulded to the outer side of the posterior end of the squamosal, with which it also freely articulates. It is seen to be present upon both sides. That this is the osseous rudiment of the hinder end of the zygomatic arch in this reptile, there cannot, Mr. Schufeldt thinks, be the shadow of a doubt.

At a recent meeting of the American Ornithologists' Union, Mr. Jonathan Dwight, Jun., read a paper on birds that have struck the statue of Liberty, Bedloe's Island, New York Harbour. He said, that, on account of its lighter colour, more birds strike the pedestal of the statue than the statue itself. The statue was erected too late in 1886 for the migratory birds. It was first struck on May 19, 1887, then late in August, when the lights were said to be put out by birds. The first date at which birds struck the statue in 1889 was August 5, when fourteen were killed. A few others were killed during the month, and a considerable number in September and October. October 24 was the last date at which birds were killed. The whole number killed this year was 690, which was considerably less than in 1888 or 1887. He found that every cold wave in the early fall was followed by migratory birds flying against the statue. Of the dead birds picked up this year, 60 per cent. belonged to one species, the Maryland yellow-throats. The remaining 40 per cent. included a great variety.

At the meeting of the Scientific Committee of the Royal Horticultural Society on December 10, Mr. Morris read a letter addressed to the Director, Royal Gardens, Kew, by Mr. R. W.

Blunfield:—"I see in the August number of the *Kew Bulletin*, an interesting account of the *Icerya purchasi*, and its depredations in South Africa, California, &c. During the past four years our gardens at Alexandria have been invaded by a coccus, which threatens now to destroy all our trees, and is causing the greatest alarm here. . . . It first appeared about four years ago, when I noticed it in quantities on the under side of the leaves of a banyan tree, but it has since spread with extraordinary rapidity, and one of our most beautiful gardens, full of tropical trees and shrubs, has been almost destroyed. A breeze sends the cottony bugs down in showers in all directions. It seems to attack almost any plant, but the leaves of the *Ficus rubiginosa*, and one or two other kinds of fig, seem too tough for it, and it will not touch them. It seems almost hopeless here for a few horticulturists to try to eradicate this formidable pest, while their indifferent neighbours are harbouring hotbeds of it, and there will have to be some strong measures taken by law to put it down." The insect in question had been referred to Mr. Douglas, and was said to be an undescribed species of Dactylopius. Spraying with kerosene emulsion was recommended, but no remedy was likely to be effectual that was not carried out universally.

THE new number of the Journal of the Royal Horticultural Society contains a full and interesting report of the proceedings of the National Rose Conference held at the gardens of the Society at Chiswick on July 2 and 3. In the same number there are the following papers: on irises, by Prof. Michael Foster; the strawberry, by Mr. A. F. Barron; strawberries for market, by Mr. G. Bunyard; the origin of the florist's carnation, by Mr. S. Hibberd; peaches and nectarines, by Mr. T. F. Rivers; on conifers, by Mr. W. Coleman; on pears, by Mr. W. Wildsmith.

A GERMAN biography of the late Dr. E. G. F. Grisanowski, by Elpis Melena, has just been published (Hanover: Schmorl und von Seefeld). The book ought to be interesting to anti-vivisectionists, as Dr. Grisanowski was an enthusiastic advocate of their ideas, and much attention is given to the subject by his biographer.

THE United States Department of Agriculture has issued the first and second of a series of illustrated papers on the North American fauna. They are by Dr. C. Hart Merriam. The first is a revision of the North American pocket mice, and includes descriptions of twelve new species and three new subspecies. The second paper contains descriptions of fourteen new species and one new genus of North American mammals.

THE sixth edition of Mr. H. Bauerman's "Treatise on the Metallurgy of Iron" (London: Crosby Lockwood and Son) has been published. Mr. Bauerman explains that, as the progress in iron and steel manufacture during the seven years that have elapsed since the last issue of the volume has been mainly in the direction of perfecting the appliances and working details of the great processes introduced between 1858 and 1878, it has not been necessary to make any very great alteration in the principal part of the text. The additions required to bring the information up to date have been placed mostly as supplemental notes at the end. The statistical details have been revised and brought up to the latest dates for which returns are available.

IN a recent paper on zoogeography, in *Humboldt*, Dr. Lampert states that a good many wolves are still captured in the east and west provinces of Germany, *e.g.* about fifty annually in Lorraine. In France, 701 wolves were destroyed in 1887; in Norway, only 15. It is estimated that in Russia the yearly loss in domestic animals through wolves is over £2,000,000, and the loss of game from the same cause, over £7,000,000. The German mole swarms, apparently, in the neighbourhood of Aschersleben, where 97,519 individuals were taken last year, and rewards amounting to £97 were paid. In great part of Germany, however (Upper and Lower Bavaria, East and West Prussia), it is not met with. Mecklenburg and Pomerania are its northern limits, at present. The beaver is nearly extinct in Germany, but a new settlement of thirty individuals was recently discovered at Regenwehrsberg, not far from Schönebeck, on the Elbe. A recent catalogue of diurnal birds of prey in Switzerland (by Drs. Studer and Fatio) gives thirty-two species. The disappearance of the golden vulture is here noteworthy. Early in this century it was met with in all parts of the Alpine chain; whereas now, only a very few individuals survive on the inaccessible heights of the Central Alps.

AN interesting inquiry into prehistoric textiles has been recently made by Herr Buschan (*Arch. für Anthrop.*) He examined tissues with regard to the raw material used, to their distribution in prehistoric Germany, to their mode of production, and to their alteration by lying in the ground. With certain chemical reagents he was able to distinguish the various fibres, though much altered. The oldest tissues of Germany (as we now know it) come from the peat-finds of the northern bronze period. On the other hand, some articles of bone found in caves of Bavarian Franks, and evidently instruments for weaving or netting (bodkins, knitting needles, &c.), show that already in the Neolithic period textiles were made. The art of felting probably preceded that of weaving. Herr Buschan sums up his results as follows: (1) in the prehistoric times of Germany, wool (mostly sheep's) and flax were made into webs, but no hemp; (2) the use of wool preceded that of flax; (3) the wool used was always dark; (4) most of the stuffs were of the nature of huckaback (none smooth); (5) the textiles have, on the whole, changed but little in course of time. The author has some interesting observations on the oldest kinds of loom. The pile-builders on the Pfaffiker, Niederwyl, and Boden Lakes, were busy weavers; and they knew how to work flax fibres not only into coarse lace, fish nets, or mats, but into such finer articles as fringes, coverlets, embroidery, and hair-nets.

IN a recent Consular Report from British North Borneo, an account is given of the explorations for gold which were made in the territories of the British North Borneo Company last year. The main obstacle had always been the difficulty of ascending the river, which is full of shallows and rapids, and of forwarding supplies of provisions, as the country is totally uninhabited, and does not afford supplies of any kind whatever. Striking into the forest at a point in Darvel Bay, which was judged to be nearest to the desired district, Mr. Skertchly crossed three sharp ridges of mountains, and at length struck the higher Segama, at a place some 250 miles inland from its mouth. The track is only 31 miles long, but great difficulty was experienced in bringing up provisions, as, owing to the rocky and mountainous nature of the ground, animals could not be used for transport, and everything had to be carried, at considerable expense, on men's backs. Payable gold was found soon after the Segama was reached, and the higher the river was ascended the more there was, but it was patchy and uncertain, and, so far, no reefs are reported, the gold being almost entirely in the river-bed. It is now certain, says the Consul, that payable gold exists, but whether the extent of country it is found in is large or small has yet to be ascertained, while the expense of conveying provisions to the gold-fields will require gold to be abundant to make it worth while working, unless an easier path is found. Mr. Skertchley was five months and a half in the forest without coming out once, and it was mainly owing to his foresight in arranging details, and his perseverance in carrying on the expedition, that success was due.

THE Annual Report of the Conservator of Forests at Singapore refers at great length to the difficulty of dealing with a

grass called *lalang* (*Imperata cylindrica*, Cyr.), which is not only useless, but very injurious, both by reason of its inflammability, and because it prevents any cultivation of the land covered by it, except with a great deal of labour and expense. Wherever the land is burnt or having been under cultivation is suffered to run to waste, it is soon covered with *lalang*, whatever may have been the previous vegetation, except where the soil is sandy, or wet, or shaded by trees. The treatment of the soil by chemicals, such as salt, sulphate of iron, &c., apart from the heavy expense connected with it, is liable to have a very injurious effect, even for many years, on the plants with which the ground is afterwards afforested. The introduction of some more actively growing plant to combat and destroy the *lalang*, has been proposed, but this would be to destroy one noxious weed by another still more noxious. When trees are tall enough to throw a shade upon the ground, the *lalang* quickly disappears, nor can it penetrate even into forest glades if but a few trees bar its progress. It is suggested, therefore, that shade trees and bushes should be gradually planted.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m., December 26 = 4h. 22m. 20s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.

(6) U Geminorum ...	Var.	Variable.	7 48 34	+22 17
(7) Neptune, Dec. 26..	—	Greenish.	4 2 21	+18 59
,, Jan. 2 ...	—	—	4 1 44	+18 57

Remarks.

(1) This is described in the General Catalogue as an exceedingly interesting object, but very faint and small; according to Hind it is variable. I have not been able to find any record of its spectrum. Continuous observations over a considerable period, even with small dispersion, may throw light upon the nature of the changes which take place.

(2) A star of Group II., in which Dunér records the bands 2–8. Bands 2 and 3 are the strongest, indicating that the star is well advanced in condensation towards Group III. As in similar stars, dark metallic lines and lines of hydrogen should receive special attention, as the stages at which these make their appearance have not yet been determined.

(3) Vogel classes this with stars of the solar type, and the usual differential observations are suggested. (For criteria, see p. 20.)

(4) According to Konkoly, this is a star of Group IV. The usual observations of the relative intensities of the hydrogen and metallic lines are required, so that the star may be placed in line with others on the temperature curve.

(5) This is a variable star of Group VI., but the range of variation is small (6·5–8·5). The origin of variability in stars of this group has not yet been satisfactorily explained, and there is no record of the spectroscopic changes which accompany the changes in magnitude. Further observations are therefore necessary, and it is suggested that variations in the intensities of the carbon flutings should be particularly noted. The star was at minimum on October 23.

(6) This variable reached its maximum on December 21, and, as the period is only 86 days, observations may be made from maximum to minimum, providing that sufficient optical power is employed. The magnitude ranges from about 9 at maximum to 14 at minimum. The colour is stated to vary from white at maximum to reddish at minimum. The spectrum has been described as continuous (probably near maximum), but the colour-changes indicate that considerable variations in the spectrum may also be expected.

(7) The spectrum of Neptune was first observed by Secchi, in 1869. He noted that there were three broad dark bands, which were nebulous at the edges, and that there was a remarkable absence of red light. Vogel gave a more detailed account of the spectrum in 1872 (*Bothkamp Beobachtungen*, 1872, p. 71). The bands then recorded were as follows:—

Wave-lengths.			Remarks.
597	...	...	End of spectrum.
565·7	...	...	End of a wide dark band.
556	...	...	Very feeble band.
540	...	...	Middle of the darkest band.
518	...	...	Faint band.
513	...	...	,,
507	...	...	,,
485·8	...	...	Middle of a dark band.
477	...	...	Middle of a wide dark band.

The whole spectrum is very similar to that of Uranus. The proximity of the edges of some of the dark bands to the bright flutings of carbon and manganese led Prof. Lockyer to suggest that in Uranus and Neptune we might have to deal with the radiation of those substances, the dark bands being produced by contrast. Acting on this suggestion, I made observations of Uranus with a 10-inch equatorial, and afterwards, in conjunction with Mr. Taylor, with Mr. Common's 5-foot reflector. Direct comparisons certainly showed coincidences of the flutings of carbon with luminous parts of the spectrum. No solar lines were visible, but Dr. Huggins has recently photographed the spectrum, and found nothing but solar lines. In a recent observation of Neptune, I thought the bright flutings were more evident than in Uranus, but I have not had an opportunity of making comparisons. Further observations with reference to the existence of bright flutings are suggested. A. FOWLER.

VARIABLE STAR IN CLUSTER G.C. 3636.—Prof. Pickering writes (*Astr. Nachr.*, 2941) that photographs are being taken at Wilson's Peak, Southern California, with a telescope of 13 inches aperture. Four photographs, with exposures of about one hour each, were taken of the above cluster, whose position for 1900 is R.A. 13h. 37m. 35s., Decl. + 28° 52′·9. A star about twenty seconds south of the centre of the cluster was found to be much brighter on May 21 and June 8, 1889, than on May 31 and June 17, 1889. Two maxima seem to be indicated by the photographs separated by an interval, during which the star becomes comparatively faint. Visual observations made at Cambridge Observatory since June appear to confirm this variability.

CHANGES IN LUNAR CRATERS.—A few observations made by Prof. Thury (*Astr. Nachr.*, 2940), of craters in the terraced ring of Plinius, indicate some striking changes. On November 1, Plinius presented the same aspect as that described in 1882 by MM. Elger, Gaudibert, and H. Klein. Two craters, cutting one another, appear in the middle of the ring, and it is thought that one of these was not visible in the middle of September. The central opening seems to have been enlarged, for on November 1 its diameter was estimated as at least one-third of the total crater, whereas in September the diameter of the opening was rather less than one-fourth of the total diameter.

The interpretation put by Prof. Thury upon these appearances is that in the centre of Plinius there are two small craters, the aspect of which is modified by the different amounts of snow and ice about them. Emissions of heated gas and vapour would affect considerably the state of the lunar surface, for if, in the beginning of an eruption, water-vapour were predominant, it would be immediately condensed around the crater, forming a circular field of snow, so that the apparent enlargement of the opening may be due to the melting of the snow surrounding it by the hot gases emitted.

SIR HENRY ROSCOE ON TECHNICAL EDUCATION.

LAST week we referred to an address delivered by Sir Henry Roscoe at Goldsmiths' Hall on Tuesday, December 17, after the distribution of the prizes and certificates to the students of the City and Guilds of London Institute. He spoke as follows:—

In his admirable address delivered last year on a similar occasion to the present, Sir Lyon Playfair pointed out that one of the important objects for which the City Guilds were originally founded was to develop and restore arts and sciences,

and act as teachers to pupils. In the ancient charters the word "Universities" is used for the modern designation of Guild. University simply means a teaching corporation, whether for professional or trade purposes. In both cases the teacher is termed a "master," and the pupil an "apprentice" from *apprendre*, to learn. The function of teaching by the Guilds was gradually lost. The master became the capitalist, the pupil the workman. The capitalist does not consider it part of his duty—quite the contrary—to teach the workman his craft, and thus the latter, though handy in one branch, never becomes a craftsman; intelligence is wanting, and the industry suffers when placed in competition with that for which the craftsman has been intelligently trained.

But now the Guilds have recovered their long lost ground, and by a natural process of evolution they are now engaged separately and collectively in nobly carrying out the work for which to a great extent they were originally constituted.

This new departure, or rather this recurrence to the ancient type, we know as technical education, and we define it as the instruction in those arts and sciences which underlie the practice of the industry or trade, this instruction being given in the technical school.

No attempt is there made to teach the trade or industry itself; this is done, and can only be done, in the factory or workshop. The school teaches how to make the best article; the workshop, how to make that article cheapest. The school ignores economical production, whilst this is the all-important factor in the workshop.

In my remarks this evening I propose to consider how the Guilds are now carrying on their work, and to point out the relation which that work bears to the general question of technical education in the country, which is now acknowledged on all hands to be one vitally affecting our industrial supremacy amongst the nations.

This acknowledgment has now received a national recognition in the passing of the Technical Instruction Act of last session of Parliament, and this has materially changed the whole aspect of affairs. *Now* technical instruction, which has hitherto been sporadic may become systematic, for private effort has received national authorization, and sooner or later a complete scheme for technical instruction must be forthcoming.

The commencement of such a scheme has indeed already been made by the efforts of the City Guilds. Your Institute, with its various branches, is the nucleus of such a system, the importance of which will perhaps only be recognized when the history of this great educational movement comes to be written.

Starting from small beginnings, this work has already attained dimensions which exceed the most sanguine expectations of its founders.

The extension of your technological examinations has been so rapid that now no fewer than 12,000 students are receiving instruction in 500 registered classes in 113 towns in the Kingdom, whilst 6000 students passed the examinations last year.

Of the value of these examinations as stimulating a knowledge of the *rationale* of practical processes there can be no doubt. The age of empiricism is past, rule-of-thumb is dead, and a new rule, that of scientific training or organized common-sense, has taken its place.

These examinations serve to spread that scientific training amongst the masses of our population, and though they do not accomplish *all*, they accomplish much, and the classes if not all first-rate are still vastly better than none at all, and it is satisfactory to note that the employers of skilled labour are beginning to find out that the men thus trained are of greater value than those who have not had such training.

To quote one example of this among many, a pupil of the Manchester Textile School gained at the last examination the silver medal in honours. He was simply a "cotton operative," but since that time he has obtained the post of manager of 1170 looms under a large manufacturing firm, and the determining factor in his success over a great number of competitors was his possession of the silver medal first-class certificate in honours of this Institute.

But, after all, the attendance on these classes is only the beginning. A more thorough training is needed; for this the Institute has founded the admirable model "Intermediate" Technical School in Finsbury, where the course is a real preparation for entering the workshop, and thus the pupils begin industrial life under more favourable conditions than otherwise would have been the case.

It is much to be hoped that the Institute may not only be able to continue grants to this most useful school, but may see its way to plant other similar schools in various parts of the metropolis, which after all is the greatest industrial centre in the Kingdom.

But the Institute does not stand alone in carrying on this great work of raising up the true craftsman, and thus helping to keep down that danger to our overcrowded centres of population—the great army of unskilled labour. The Guilds are separately taking up the question, and if we may deplore the withdrawal of some from the general scheme, we may well commend their efforts in other directions. Witness the foundation by the Company in whose hall we are now assembled of a great technical and recreative institute at New Cross, which bids fair to become a centre of light and leading in a district dark and backward.

Again, look at what the Drapers' Company have done, and are doing, at the East End to place the People's Palace on a sound financial basis; or at the still greater work, if such things can be compared, which the Clothworkers' Company has done in Yorkshire and other districts to place upon sure scientific foundations the clothworker's craft.

Amongst these efforts to raise the industrial capabilities of our population we must not forget the scheme of the Charity Commissioners for the application of the property of the City of London charities. This arose out of an Act passed six years ago at the instance of my friend Mr. Bryce, which directed that the general funds of these charities should be applied to the benefit of the poorer part of the population.

No less a sum than £50,000 per annum is thus applicable, and the scheme lately put forward by the Commissioners for the appropriation of this sum is, on the whole, an admirable one, which may, if wisely worked, end in the creation of what may be termed a popular technical University for London. The value of such an organization as is thus proposed will be appreciated by those who have some knowledge of how these things are managed on the Continent, and in how chaotic a state is the whole of London education beyond the rank of the primary school.

All these efforts are truly "signs of the times;" they point to the recognition by the better endowed that not merely is it their duty, but their self-interest, to see that those who have the power know how to use it wisely, for it is on this that our national stability and progress depend.

But it is not enough simply to educate the craftsman; his employer needs it equally, if not more, and this task is, perhaps, a more difficult one, for as the Royal Commissioners on Technical Education report, "Englishmen have yet to learn that an extended and systematic education, up to and including original research, is a necessary preliminary to the fullest development of industry," and this necessity your Council have fully acknowledged, for, at the inauguration of your Central Institution, Lord Selborne said:—"It is, however, in the appreciation of, and in the facilities for higher technical instruction, that we in this country are most deficient, and it is to supply this want that the Central Institution has been established, . . . in which new and increased facilities will be afforded for the prosecution of original research, having for its object the more thorough training of the students and the elucidation of the theory of industrial processes."

I do not think that one could more emphatically or more clearly define the character of the work needed for the highest instruction of the future leaders of industry, than Lord Selborne has done in these words.

Now, the question arises, Is the Central Institution accomplishing the ends thus clearly marked out? It must be admitted that the supply of students has hardly been equal to the expectations formed by its friends at the outset. But if the work done is of a high class, and if those who come within its walls are there fitted for discharging the higher duties which modern industry requires, we may be satisfied, for the fact is that the demand for high-class technical instruction has yet to be created. Other difficulties beset this particular kind of teaching. One is that, as in many new institutions, the students enter ill-prepared, and thus the instruction is forced into elementary lines, and the time which can be given to higher work materially shortened.

A second, is that of hitting off the happy mean between the teaching of theory and that of practice, and in order that this essential may be accomplished, it is necessary that the teachers giving this higher technical instruction should be men who are well known and respected in their several professions, and not mere schoolmasters. In other words, that they shall know the

practice as well as the theory of the subjects they profess. Such men, as far as I am able to judge, your Council has found in the present able staff of professors.

Then again, in measuring the success of such a College, it must be remembered that it is intended for the *élite* of the industrial world, and that, as individual attention must be paid to each student in the laboratories and drawing-offices, the highest technical instruction of crowds is impossible.

Little seems hitherto to have been done in the way of training technical teachers, and for the obvious reason that the demand for such is very limited, whilst that for competent men to enter a more practical career is great.

But whether the College is training teachers, or those who are to carry out the lessons of such teachers into practice, does not matter. The object is to train men who can improve our present industries, and raise up new ones; and this may be accomplished by either or by both methods. Neither the one nor the other can, however, succeed unless the student of technology has a firm grasp of the scientific principles upon which his industry is based.

It is useless, and worse, to attempt to teach the applications to pupils to whom the science itself is an unknown quantity.

Hence arises the question, How and where can the preliminary science training be best given? and the answer to this raises many difficult and some delicate matters.

First, however, let me disabuse your minds of a notion which may become general, and, if so, harmful—namely, the new Metropolitan Polytechnic Institutions, as they are called, can overtake this highest and most important kind of education. Do not let us fancy that the establishment of these no doubt very valuable institutions is the ultimatum to be aimed at in technical education, or imagine that they can attempt to do what is done in Germany, France, or Switzerland by institutions bearing the same name. I look upon it as a misfortune that, by mere chance, the name of the old Institution in Regent Street, known to fame as the home of the diving-bell and of Prof. Pepper's Ghost, should have been retained for institutions which neither resemble it nor the high schools which form so marked a feature in the Continental educational system. These latter are in our country rather represented by the scientific departments of our Universities, and by those of the metropolitan and local University Colleges, by the Royal Normal School of Science, and by your own Central Institute. We cannot too clearly understand that whatever success attends the foundation of these Metropolitan Polytechnics—and no one more cordially wishes them success than I do—the work of the centres of the highest education still remains; indeed, the greater the popularity of the lower institutions, the greater the need and scope for the higher ones.

The rapid growth in London of this idea of the importance of handicraft and recreative education is most remarkable, and for this stimulus we are almost wholly indebted to Mr. Quintin Hogg.

The effect of this movement upon your Institute has been severely felt, for it is clear that, whereas seven or eight years ago the enthusiasm of the City Companies was strongly in favour of the higher technical education in the Continental sense, it is now all for this newer and more popular, I will not say less useful, form of handicraft and recreative instruction.

It is a fact which may as well be clearly stated, that the Central College cannot do all it might do for want of a few thousands, and that the scheme of technological examinations is crippled by the loss of the support of those who at first nobly contributed towards these objects.

The Drapers prefer to support more popular institutions at the East End, and the Goldsmiths do likewise in regard to their own institution at New Cross, so that there is no doubt that the interest formerly felt in the general and collective work of the Institute is distinctly on the wane.

Well, ladies and gentlemen, a consideration of these patent facts leads one to the question, How are these things to go on? Are we never to have "law and order"—about which we have heard enough in other matters—introduced into affairs educational?

And in what I am about to say, let me premise that I merely express my own individual opinion as an independent observer, anxious only for the success of the good cause which we all have at heart. Then may I say that I am dead against a cut-and-dried system of Governmental education such as we see in other countries. I am all for stimulating and developing local effort to local requirements, and it is because I am fully aware of the dangers of centralization, and desire to promote adaptability to local needs, that I gave my hearty support to the Government Technical Instruction Bill as amended in the House of Commons, in which the power of the locality to work out its own educational salvation is fully safe-guarded.

But holding these views I see clearly that there are things which can only be satisfactorily accomplished by a central authority.

That our primary education can only be properly conducted on a national basis has been admitted for more than a quarter of a century; so it will be with the higher or secondary education, whether technical, commercial, or professional—we *must* have a system. As I have said, the foundation of your Institute was the beginning of such a system for technical instruction; but has it not already outstripped the bounds of your control? Can it be satisfactorily worked in the future on its present lines?

Let us look at the matter from an independent point of view. We have now three Government Departments charged with educational work—the Education Department for Elementary Instruction, the Science and Art Department, and the Charity Commissioners. One of the most important steps which could be taken to bring these under effective control is the appointment of a Minister of Education, of Cabinet rank, who would be in close touch with every part of our now discordant educational system. But that is not the immediate question before us.

This refers more especially to the desirability of consolidating the Science and Art Department. As you know, this controls and stimulates, in what I think we may allow to be a satisfactory manner, the teaching of elementary science and of art throughout the country. Would it not conduce to the benefit of the country, if the Guilds' technological examinations were to be undertaken by the Department, and thus placed on a national basis? Several of the subjects now included in the Directory of the Department, on which grants are made, are of a distinctly technical character, and therefore no objection can be raised that the other subjects now under the Guilds Institute cannot equally well be placed under the Department.

The benefits which would thus accrue are great and palpable, the two systems of examinations in pure and in applied science would then work side by side without friction or overlapping, and the extension of the technical examinations would be easy and certain.

If this were accomplished, I for one would strongly urge the removal of the system of payment on individual results—a method in all cases to be deprecated, but one which is especially unsuited for testing the value of technical instruction. This can be much more certainly effected by ascertaining the efficiency of the whole class, of the teacher, and of his appliances, by inspection or otherwise.

If once we get rid of this system of payment on individual results in one set of subjects, we may look forward to its ultimate extinction in the others, and no subject seems so suitable for making a beginning as that of technical instruction.

I would therefore suggest that the best means of securing the permanency and the extension of the very useful technological examinations which your Council—and all honour to them for it—have started, is to request the Government to take them over, thereby rendering the Science and Art Department more efficient, and enabling that Department to make the improvements and alterations in the system which it undoubtedly requires.

May I go one step further in these suggestions, and ask if this should be done, is it not a necessary corollary that the Central Institute should likewise become a Government Normal School for Applied Science? There is much to be said in favour of such a proposal.

The very situation, close to the Royal Normal School of Science, seems to forecast its ultimate destiny. Under separate management, no consistent or well-arranged scheme of common work is possible; brought under one direction, the essential alliance between pure and applied science, as regards teaching, becomes easy of attainment.

Students would pass and re-pass from the one school to the other, obtaining at the one the knowledge of the scientific principles, and, at the other, that of their applications.

Of the national advantages of such a fusion there can, I think, be little doubt. England would then be in possession of an institution which might, for completeness and efficiency, both as regards the *personnel* and the appliances, soon be made second to none on the Continent, and worthy of the greatest industrial nation in the world.

Your Institute would thus set itself free to extend its influence

in other directions, and could then concentrate its efforts on what is perhaps, after all, its most legitimate and most useful function—that of providing intermediate technical schools on the pattern of the Finsbury School, of which many are required in the metropolis.

The exact terms on which the Government would be prepared to take over this part of your work is a subject on which, of course, I cannot pretend to enter, but a satisfactory basis can, I do not doubt, easily be found.

Your Council would then feel that the great work which they have begun has been handed over in its full vigour to the nation, and that with the nation lies the responsibility of extending and perfecting the system which they have had the honour and the gratification of inaugurating.

If, in the foregoing remarks, I have raised a somewhat burning question about which I know there is a difference of opinion, my apology must be the importance of the subject, and the anxiety which we all feel that the technical education of our country shall be placed on a firm and enduring national basis.

A FIRST FORESHADOWING OF THE PERIODIC LAW.

It is well known that the Newlands-Mendeleeff classification of the elements was preceded by the discoveries of certain numerical relations between the atomic weights of allied elements, due to Döbereiner, Dumas, and others; but what has been almost entirely ignored is the immense advance made by M. A. E. Béguyer de Chancourtois,[1] a French geologist of note, Professor at the École des Mines, who was the first to publish *a list of all the known elements in the order of their atomic weights.*

M. de Chancourtois embodied his results in two memoirs presented to the French Academy of Sciences in April 1862 and March 1863. These memoirs have never been printed *in extenso*,[2] but extracts from them, and additional notes relating to the subject, were published in the *Comptes rendus* for 1862 (liv. pp. 757, 840, and 967; lv. p. 600), 1863 (lvi. pp. 253 and 479), and 1866 (vol. lxiii. p. 24). The first note bears the date of April 7, 1862, so that there can be no doubt as to de Chancourtois's claim to priority in this important matter.[3]

I have in my possession a thin quarto pamphlet, by de Chancourtois, entitled "Vis Tellurique: Classement naturel des corps simples ou radicaux, obtenu au moyen d'un système de classification hélicoïdal et numérique" (Paris, Mallet-Bachelier,[4] 1863), which contains nearly all the extracts from the *Comptes rendus*, together with some additional matter. It contains, also, what is absolutely essential to the comprehension of de Chancourtois's ideas, the graphic representation of his system, which is not to be found in the *Comptes rendus.*

I propose to give here a translation of the first communication to the Academy, followed by certain explanatory comments and brief extracts from the other papers:—

"Geological studies in the field of research opened up by M. Elie de Beaumont in his note on volcanic and metalliferous intrusions (*émanations*) have led me, for the completion of a lithological memoir on which I am now engaged, to a natural classification of the simple bodies and radicles by a table in the form of a helix, founded on the use of numbers which I call *characteristic numbers* or *numerical characteristics.*

"My numbers, which are immediately deduced from the measure of the equivalents or other physical or chemical capacities of the different bodies, are, in the main, the proportional numbers given by the treatises on chemistry, these being reduced to half in the case of hydrogen, nitrogen, fluorine, chlorine, bromine, iodine, phosphorus, arsenic, lithium, potassium, sodium, and silver; in other words, I either divide the equivalents of these bodies by two in the system in which oxygen is taken as 100, or multiply by two the equivalents of the other bodies in the system in which hydrogen is taken as unity.

"On a cylinder with a circular base, I trace a helix which cuts the generating lines at an angle of 45°. I take the length of one turn of the helix as my unit of length, and starting from a fixed origin, I mark off on the helix lengths corresponding to the different *characteristic numbers* of the system in which the number for oxygen is taken as unity. The extremities of the lines thus marked off determine points on the cylinder which I call indifferently *characteristic points* or *geometrical characters*, and which I distinguish by the ordinary symbols for the different bodies. The same points will evidently be obtained if we take as the unit of length the $\frac{1}{16}$ of a turn of the helix, and mark off on the curve lengths corresponding to the numbers of the system in which hydrogen is represented by unity.

"The series of points thus determined constitutes the graphic representation of my classification, which may easily be traced on a plane surface by supposing the surface of the cylinder developed; by its aid I am enabled to enounce the fundamental theorem of my system: *The relations between the properties of different bodies are manifested by simple geometrical relations between the positions of their characteristic points.*

"For instance, oxygen, sulphur, selenium, tellurium, bismuth,[1] fall approximately on the same generating line, while magnesium, calcium, iron, strontium, uranium, and barium, fall on the opposite generating line. On either side of the first of these lines we find hydrogen and zinc on the one hand, bromine and iodine, copper and lead on the other; parallel to the second line we find lithium, sodium, potassium, manganese, &c.

"Simple relations of position on a cylindrical surface would be obviously defined by means of helices, of which the generating lines are only a particular case; hence, as a complement to the first theorem, we may add the following: *Each helix drawn through two characteristic points and passing through several other points or only near them, brings out relations of a certain kind between their properties; likenesses and differences being manifested by a certain numerical order in their succession, for example, immediate sequence or alternation at various periods.*

"In order to attain a greater degree of accuracy, it is necessary to discuss the results of different measurements with respect to the same body.

"One question is all-important in this discussion; it is to know if the divergencies which occur may have causes other than the error of experiment. I reply to this question in the affirmative.

"I think that here, as in all determinations of constants which we wish to compare, they must be reduced to the same conditions. This idea seems to me the indispensable complement to the notion of an absolute characteristic number. Once the existence of this absolute number or *numerical characteristic* guaranteed by the possibility of connecting it afresh with observed facts, certain limits of variation being allowed [*literally*, varying within certain limits], we promptly arrive at Prout's law, which presents itself as furnishing a means for reducing experimental observations to a comparable state by a series of trials, without this state being even a completely defined one, but, on the contrary, in order to be able to define it. The combination of this principle with the rules for alignment allow me to give the most striking form to my invention. I am thus led to formulate the table of integral numbers, which, as I must not omit to mention, exhibits under certain aspects the *résumé* of the work of M. Dumas on this subject.

"In the construction of this table I have had recourse to the determinations of specific heats, not only as a means of control, but also to find new numbers unattainable by the methods of chemical investigation. By adopting as the constant product of specific heat by atomic weight, the number which corresponds both to sulphur and to lead, I have deduced from the series of results given by M. Regnault, purely *thermic* quotients or numbers, which take their places on my alignments in the most felicitous way. I will only quote two examples: firstly, the number 44, obtained from the specific heat of the diamond, which finds its place on the generating line of the characteristic, 12, of carbon, by the side of the characteristic, 43, which corresponds to one of the equivalents generally accepted for silicon; and another

[1] Wurtz ("The Atomic Theory," p. 170) and Berthelot ("Les Origines de l'Alchimie," p. 302) give a bare mention of de Chancourtois's name. Mendeleeff, in his Faraday Lecture (Journ. Chem. Soc., October 1889), couples his name with those of Newlands and Strecker, and shows greater appreciation of his work.

[2] M. Friedel, the eminent Professor of Organic Chemistry at the Sorbonne, has kindly procured for me the information that the original manuscripts of these memoirs are preserved in the archives of the Institut; I hope to be able to examine them at some future period.

[3] Mr. Newlands' first paper, chiefly devoted to showing that the numerical differences between the atomic weights of allied elements are approximately multiples of 8 was published on February 7, 1863 (*Chemical News*, vol. vii. p. 70); his second paper, in which he arranges the elements in the order of their atomic weights, was published on July 30, 1864 (*Chemical News*, vol. x. p. 39) See J. A. R. Newlands "On the Discovery of the Periodic Law," &c. (Spon, 1884).

[4] Now Gauthier-Villars.

[1] This is probably a misprint, as bismuth does *not* fall on the same generating line in the table.

characteristic, 36, of silicon deduced from an equivalent proposed by M. Regnault, and which is very remarkable, from its coincidence with the characteristic of ammonium.

"By the discussion, which has shown me the advisability of accepting various results hitherto looked on as scarcely reconcilable, I have been led to conceive the possibility of reproducing the *series of natural numbers* in the series formed by the numerical characteristics of the real or supposed simple bodies supplemented by the characteristics of the compound radicles formed from gazolytic[1] elements, such as cyanogen, the ammoniums, &c., and doubtless also by the compound radicles formed from metallic elements, of which the alloys offer us an example. In this natural series, the bodies which are really simple, or at least irreducible by the ordinary means at our disposal, would be represented by the *prime numbers.* It will be at once seen that there are in my table at least twelve bodies, which, like sodium (23), have characteristics which are prime numbers. This is what led me to perceive this law, which, I believe, is destined, when established, to form one of the bases for the discovery of the law of molecular attraction. The predominance of the law of divisibility by 4 in the series of my table, a predominance which is also to be found in the elements of the theory of numbers, has confirmed me in the idea—an idea in itself really simple—that there is a perfect agreement between bodies, the elements of the material order, and numbers, the elements of the abstract order of things (*éléments de la variété matérielle, de la variété abstraite*). This goal once caught sight of, it will seem natural that I should have recourse to the theory of numbers to help me attain it. It will seem not less natural that I should also have recourse to higher geometry; for the series of relations it offers cannot fail to afford resources which may enable one to establish connections between the different numerical characteristics.

"My helicoidal system in this way leads me on towards abstract views of an extremely general nature; and on the other hand it should, it seems to me, find an application in the natural[2] sciences, as a method of classification throughout their whole domain, from the series of simple bodies which forms the prototype, to the opposite extreme of our natural divisions; in it will be found, I believe, the means of bringing into connection simultaneously, and by all their characters, the different terms of those parallel series, orders, families, genera, species, and races, in each natural kingdom, of which men of science have in vain tried to show the affiliation. In geology, as is evident, the application is implicit.

"Whatever may be the import of these considerations, and to return to the principal object of the present memoir, I think that the efficacy of the helicoidal system will be admitted as a means towards hastening the advent of the time when chemical phenomena shall be amenable to mathematical investigations.

"My table, by the distribution of bodies in simple or coupled series, by its indication of the existence of conjugate groups, &c., traces a plan for diverse categories of syntheses and analyses already executed or to be executed; it draws up very definite programmes for the execution of several researches which are exciting attention. Will not my series, for instance, essentially chromatic as they are, be a guide in researches on the spectrum? Will not the relations of the different rays of the spectrum prove to be derived directly from the law of numerical characteristics, or *vice versâ?* This idea, which occurred to me before we were taught the identification of the lines in the spectrum, and the admirable applications of this discovery, seems to me now even more than probable. Finally, looking upon it only as a concise representation of known facts, and reducing it to the points which offer no matter for discussion, the geometrical table of numerical characteristics affords a rapid method for teaching a large number of notions in physics, chemistry, mineralogy, and geology. I hope, therefore, that my natural classification of the simple bodies and radicles being capable of rendering manifold services, will need, like every object in habitual use, a name of easy application; hence, on account of its graphic representation and its origin, I give it the significant name of *telluric helix.*"

It will be well to point out immediately that M. de Chancourtois's system assigns to the *numerical characteristics* of the elements a general formula of the form $(n + 16n')$, where n' is necessarily an integer;[3] and his table thus brings out the fact that the differences between the atomic weights of allied bodies approximate in many cases to multiples of 16.[1]

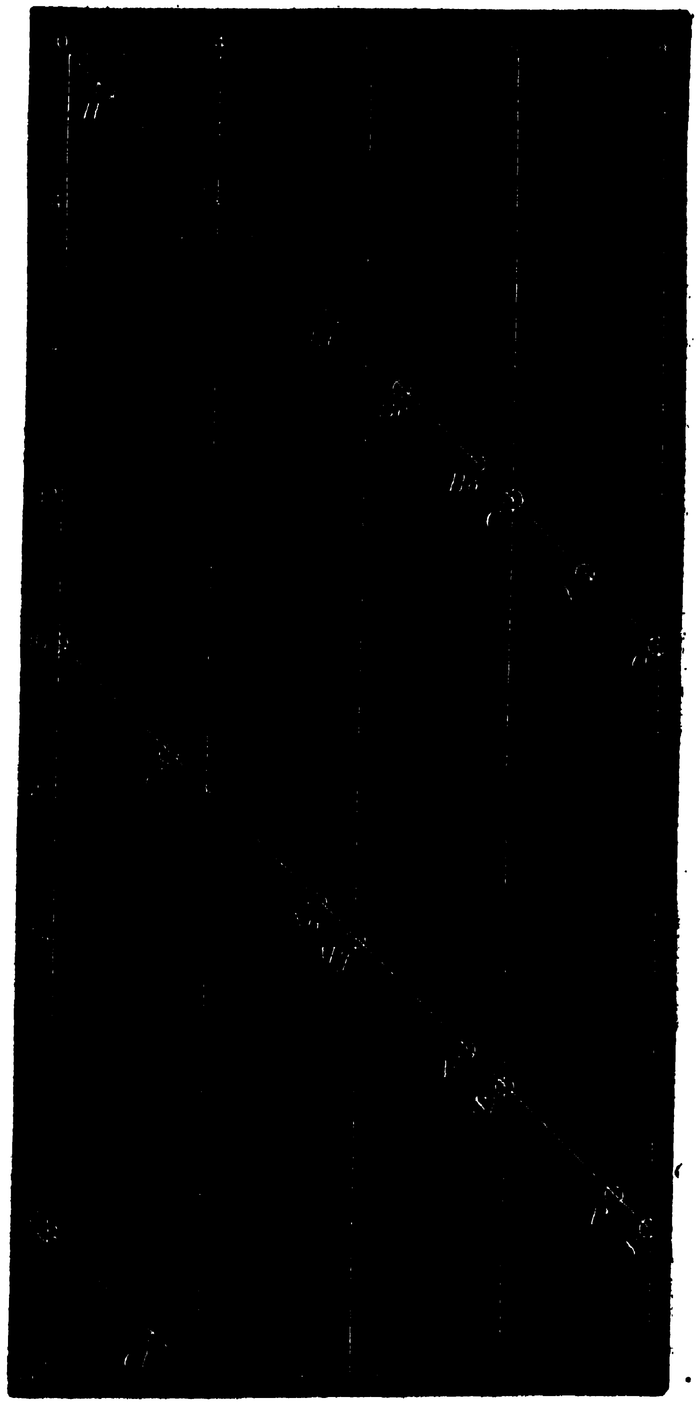
Thus we get the parallel series of which our author speaks—

$$\overset{\text{Li}}{7} \ \ldots\ 7 + 16 = \overset{\text{Na}}{23} \ \ldots\ 7 + 2 \cdot 16 = \overset{\text{K}}{39} \ \ldots\ 7 + 3 \cdot 16 = \overset{\text{Mn}}{55}$$

$$7 + 5 \cdot 16 = \overset{\text{Rb}}{87}.^{2}$$

$$\overset{\text{O}}{16} \ldots 16 + 16 = \overset{\text{S}}{32} \ldots 16 + 4 \cdot 16 = \overset{\text{Se}}{80} \ldots 16 + 7 \cdot 16 = \overset{\text{Te}}{128}.^{3}$$

As we glance at the first two turns of de Chancourtois's helix, we ask ourselves if the discovery of Newlands and Mendeleeff does not lie before us.



But the discovery of the "octaves" or "periods" cannot be ascribed to our author, although it seems almost impossible that chemists should not have perceived their existence on looking at his table.

[1] Metalloid.

[2] The term includes physical science.

[3] n is always represented in the author's table as integral, but he expressly states that he looks on this as by no means necessary. "The construction of the telluric helix rests on the use of proportional numbers derived from experiment. It would remain valid with fractional numbers, and often the helicoidal alignments would be even more easily applicable to these than to integers" (*Comptes rendus*, vol. liv. p. 842).

[1] This fact, now familiar, has again been noticed by your correspondent, Mr. A. M. Stapley, in the issue of November 21, 1889.

[2] The atomic weight of rubidium should be 85. We may notice that the author gives as probable also Cs = 135 = 7 + 8 . 16, which is thus placed on the same generating line.

[3] Certainly too high a value; according to Brauner, the exact atomic weight of tellurium remains to be determined.

Three important points, however, do exist in common between de Chancourtois's system and that of Mendeleeff:—

Firstly, all the known elements are arranged in the order of their combining weights.

Secondly, the combining weights chosen as best suited to bring out clearly the numerical relations existing between them are those adopted by Cannizzaro in 1858, a striking fact when we recollect that de Chancourtois wrote only in 1862, at a date long before these numbers had gained anything like general acceptance.

Lastly, an attempt is made to show that simple numerical relations exist, not only between the combining weights, but between all the measurable properties (*toutes les capacités physiques et chimiques*) of allied elements.

The reasons for the neglect of de Chancourtois's researches and the oblivion into which they have fallen are not far to seek. His style was heavy and at times obscure, and, moreover, his ideas were presented in a way most unattractive to chemists.

A geologist by profession, de Chancourtois had been powerfully impressed by the facts of isomorphism in the case of the feldspars and pyroxenes, which form such important constituents of the volcanic rocks he was studying; and he was thus led to seek for a system of classification which should bring out some simple relationship between the elements they contained.

To quote from his paper (*Comptes rendus*, vol. liv. p. 969): "The parallelism of the groups of manganese (7 + 3 . 16) and iron (8 + 3 . 16), of potassium (7 + 2 . 16) and calcium (8 + 2 . 16), of sodium (7 + 16) and magnesium (8 + 16), is the origin of my system"; and again, suggesting the expediency of adopting 55 (= 7 + 3 . 16) as a *characteristic* for aluminium, which would bring the element on the sodium and potassium generating line, "this would render perfect the parallelism between the elements of the feldspars and the pyroxenes, the starting-point of my system" (*Comptes rendus*, lvi. p. 1479).

Thus the correct idea of seeking for a relationship between the combining weights of isomorphous elements was marred by a somewhat imperfect comprehension of the facts of isomorphism. No chemist would certainly have tried to show any close relationship between aluminium on the one hand and the group of the alkalies on the other, notwithstanding their union in the feldspars and pyroxenes; and a suggestion of this kind served to cast discredit on de Chancourtois's really important views.

Notwithstanding his frequently eccentric ideas, de Chancourtois had the merit, so rare in an inventor of this stamp, of not considering his system as final. We cannot do better than let him speak for himself; and quote the conclusion of his last paper on the subject (*Comptes rendus*, lvi. p. 481):—"In presence of the rapid increase in the list of elements which engage the attention of chemists and physicists, it has become urgent to unite in one synthesis all the notions of chemical and physical capacities, of which the exposition would otherwise become an impossible task.

"It is, therefore, perhaps not unnecessary to recall the ideas of Pythagoras, or what I may better term the *Biblical truth* which dominates all the sciences, and of which I propose to make practical use by the following concrete example,[1] the first general conclusion of my essay:—

"THE PROPERTIES OF BODIES ARE THE PROPERTIES OF NUMBERS.

"It is easily perceived, that a helicoidal system of some kind or another, which is necessarily a graphic table of divisibility, offers the most convenient means for rendering manifest the relations between the two orders of ideas. It is evident, also, that the particular system which I have adopted brings into relief the relations of the most important and usual of the properties of matter, because the case of divisibility by 4, which is the basis of my plan, is the first which presents itself in arithmetical speculation after the case of divisibility by 2, to which there corresponds directly, as one perceives by a first glance at my table, the existence of the natural couples of elements, with consecutive odd and even characteristics.

"I hope, therefore, that the *telluric helix* will offer, until it is replaced by some more perfect invention, a practical framework, a convenient scale, on which to set down and compare all measurements of capacities, whatever the point of view which may be taken, whatever elasticity or variation, whatever interpretation may be given to the *numerical characteristics*, by which these capacities must always be represented.

[1] The French is *vulgarisation*, literally *popularisation*.

"The development in a plane of the cylinder ruled into squares, with the circumference at the base divided into 16 equal parts, seems to me, in a word, to be a *stave* on which men of science, after the fashion of musicians, will note down the results of their experimental or speculative studies, either to co-ordinate their work, or to give a summary of it in the most concise and clear form to their colleagues and the public."

Lothar Meyer has noted down his classification in the form of a helix,[1] and Dr. Johnstone Stoney, F.R.S., has shown that the numerical values of the atomic weights may be expressed geometrically as functions of a series of integral numbers by points all lying approximately on a logarithmic spiral.

But no simple mathematical formula has so far been discovered to express the relationships of the atomic weights accurately—*i.e.* within the limits of experimental error, and de Chancourtois's predictions still remain but incompletely fulfilled.

I need not comment further on the remarkable breadth and originality of our author's views, taken as a whole. Strange to say, it was only a year or two before his death that he heard, through a colleague, of the immense development they had undergone; nor did he ever set up any claims to priority. But when we speak of the greatest generalization of modern chemistry, and recall the names of Newlands and Mendeleeff, it is only just that we should no longer forget their distinguished precursor, de Chancourtois.

P. J. HARTOG.

SCIENTIFIC SERIALS.

American Journal of Science, December.—The temperature of the moon, by S. P. Langley, with the assistance of F. W. Bery. With this memoir the authors complete the researches begun at the Allegheny Observatory in 1883 and continued during the next four years. The main outcome is that the mean temperature of the sunlit lunar surface is much lower than has been supposed, most probably not being greatly above 0° C.—The Lower Cretaceous of the South-West, and its relation to the underlying and overlying formations, by Charles A. White. The chalk formations constituting the so-called "Texas Section" are here referred to two natural divisions, which may be designated the Upper and Lower Cretaceous respectively, although not necessarily the exact equivalents of the corresponding European strata. Their fossil contents show that each represents an unbroken portion of Cretaceous time, while the palæontological contrast between the two indicates that there is a time hiatus between them. But this hiatus is no greater than exhibited in others of the mountain uplifts in the same region, and not so great as it is in some cases.—On the hinge of Pelecypods and its development, with an attempt toward a better subdivision of the group, by William H. Dall. Three fundamental types of hinges are described, and on these is based a new classification comprising the three orders of Anomalodesmacea with five sub-orders, Prionodesmacea with eight sub-orders, and Teleodesmacea with eleven or more sub-orders.—The magnetism of nickel and tungsten alloys, by John Trowbridge and Samuel Sheldon. The question is here discussed whether nickel and tungsten alloys magnetized to saturation increase in specific magnetism as different kinds of steel alloyed in small proportions with tungsten or wolfram are known to do. The tabulated results show that tungsten greatly increases the magnetic moment of nickel, if the alloy be forged and rolled, but has small influence if simply cast; nor do changes in the amount of tungsten appear to cause corresponding changes in the magnetic properties of the alloy.—Note on the measurement of the internal resistance of batteries, by B. O. Peirce and R. W. Willson. The authors' researches show that the value of the resistance of a cell obtained by the use of alternate currents is always smaller than that obtained by other methods, but the application of the method of alternate currents "fatigues" all but the so-called constant cells. In most cases there is a tendency in the internal resistance to *decrease* as the strength of the current which the cell is delivering increases.—Papers were contributed by Robert T. Hill and R. A. F. Penrose, Jun., on the relation of the uppermost Cretaceous beds of the Eastern and Southern United States, and on the Tertiary Cretaceous parting of Arkansas and Texas; by W. E. Hidden and

[1] "Die modernen Theorien der Chemie," iv. Auflage, p. 137; English translation, p. 118.

J. B. Mackintosh, on sundry yttria and thoria minerals from Llano County, Texas; and by O. C. Marsh, on the skull of the gigantic Ceratopsidæ.

THE *American Meteorological Journal* for November contains the first part of an article on "Theories of Storms, based on Redfield's Laws," by M. H. Faye, member of the French Institute. In support of his "whirlpool" theory, he urges that meteorologists have constructed a theory of storms on the basis of a single fact, viz. that storms which burst over a region cause a fall of the barometer there, and he points out that starting with the idea of an ascending column, exercising an aspiration below, a thing is invariably produced which neither turns nor progresses. Mr. A. L. Rotch contributes the first part of an article on "Meteorology at the Paris Exposition," dealing with the instruments exhibited in the French Section. Among the most interesting are (1) the actinometers exhibited by the Montsouris Observatory; (2) the Richard actinometer, which has bright and black bulbs *in vacuo*, connected with two thermometers, by which curves are traced giving at each instant the radiation from the sky, both at night and day; (3) the Richard anemographs, which have, instead of the usual Robinson cups, a fan wheel formed of six blades inclined at 45°, and fastened to a very light axis, one revolution of the wheel corresponding to one metre of wind. Parrigou-Lagrange's anemometer (NATURE, vol. xxxvii. p. 18), giving the vertical component of the wind, was also exhibited. M. Baudin showed some very fine standard thermometers, and Mr. Rotch describes various other instruments, such as hygrometers, aneroids, &c. Dr. F. Waldo continues his discussion of the "Distribution of Average Wind-velocities in the United States." The present article deals with the comparison of average wind-velocities with other elements, *e.g.* with barometric minima. Lieutenant Finley contributes State tornado charts for Arkansas, North Carolina, and Dakota.

THE numbers of the *Journal of Botany* for November and December are chiefly occupied with articles of special interest to students of British botany. Mr. Thiselton Dyer gives a very interesting biography of the late Mr. John Ball, F.R.S., first President of the Alpine Club, Under-Secretary of State for the Colonies under Lord Palmerston, an ardent explorer in all the four quarters of the globe, and a botanist of wide and varied knowledge. In the December number is a remarkable article on the disappearance of British plants, mainly through the depredations of collectors.

Rendiconti del Reale Istituto Lombardo, November 1.—Physical researches on the lakes of North Italy, by Prof. F. A. Forel. During a visit to this lacustrine region, last autumn, the author studied the waters of Lakes Maggiore, Como, Piano, and Lugano, with a view to determining their temperature, colour, and transparency, as compared with the analogous properties of Lakes Lucerne and Geneva. The results, which are here tabulated, show that the temperature is generally higher, and the colour deeper in the Italian than in the Swiss lakes, while the transparency is about the same, except in the shallow Lake Piano, where the temperature is lower and the transparency less than in any of these basins.—Meteorological observations made at the Brera Observatory during the month of September. These observations include records of temperature, barometric pressure, atmospheric moisture, rainfall, direction of the winds, and cloudinéss.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 12.—"The Relation of Physiological Action to Atomic Weight." By Miss E. J. Johnston, University College, Dundee, and Thos. Carnelley, Professor of Chemistry in the University of Aberdeen. Communicated by Sir Henry Roscoe, F.R.S.

A. *As deduced from the Character of the Elements occurring naturally in Living Organisms.*—It is shown (*a*) that life is associated with a low atomic weight, so that elements with an atomic weight of 40 and under are required by the living organism, whereas those of an atomic weight greater than 40 are more or less inimical to life (compare Sestini, *Gazz. Chim. Ital.*, vol. 15, p. 107). (*b*) That the eight elements which enter most largely into the composition of the earth's crust, and which, therefore, are the most easily accessible to the living organism, are all included, with the exception of aluminium, in the fourteen elements which are required by the living organism.

A consideration of the exceptions (viz. Li, Be, B, Al, and Fe) to the first rule and of all the known facts bearing on the question leads to the conclusion that, "*The degree of necessity of an element to the living organism is a function of, first, its atomic weight, and, second, its accessibility to the organism.*" An element may be inaccessible to living organisms either because it is rare (*e.g.* Li and Be); or because, though moderately common, it has a very limited distribution (*e.g.* B); or because, though plentiful and widely distributed, it does not occur in nature in a form in which it can be assimilated (*e.g.* Al, on account of the insolubility of its native compounds).

That elements which are necessary to life must be readily accessible is self-evident, but that living organisms should require elements with low atomic weights, while elements with high atomic weights are inimical to life, is not so evident. This, however, may be due, in part at least, to the fact that the elements with low atomic weights are on the whole the most common elements (as shown by Gladstone, *Phil. Mag.* [5], vol. 4, p. 379; compare also Mendeljeff, *Zeit. f. Chem.* vol. 5, 1869, p. 405), and therefore the most accessible, so that *from the first the elements utilized in vital processes have been those which have been the most accessible, and therefore those with the lowest atomic weights.*

B. *As deduced from the Toxic Action of Compounds administered artificially.*—In view of the somewhat discordant results obtained by previous observers as to the relation between atomic weight and physiological action, the authors have reinvestigated the subject as carefully as possible. Their experiments have been made partly with fish (sticklebacks) and partly with aërial micro-organisms, the salt being administered by solution in the medium (water or Koch's jelly) in which the organism lived. the following conclusions are drawn from the results of about 800 experiments which the authors have made during the two years they have worked on this subject:—

1. *With corresponding compounds of elements belonging to the same sub-group, the toxic action*[1] *alters regularly* (i.e. *increases or diminishes*) *with the atomic weight.*

2. *In almost all cases this alteration takes place in such a way that the toxic power increases with the atomic weight.* (This is analogous to increase in toxic action in homologous series of carbon compounds.)

3. *Elements belonging to odd series* (Mendeljeff's classification) *are much more toxic than the corresponding elements of even series.*

4. *Other things being the same, the greater the ease of reducibility of an element from a state of combination to the free state the greater its toxic action.* (Applicable to compounds of odd as compared with those of elements of even series, and also to compounds of the elements of odd series belonging to the same group when compared with one another.)

5. *Other things being the same and the compounds comparable, the greater the heat of formation of a compound from its elements the smaller is its toxic power*; or, in other words, the greater the stability of a compound the smaller its toxic power. (Applicable to elements belonging to odd series; data for those belonging to even series are wanting or are too incomplete.)

There is a close connection between rules 3, 4, and 5.

6. *Lithium forms a very marked exception to all the above rules*, for notwithstanding its very low atomic weight, its difficult reducibility to the free state, the fact that it belongs to an even series, and the great stability of its compounds, as indicated by their relatively great heat of formation, its toxic power is, nevertheless comparatively very great. This exceptional character of lithium, however, is not limited to its physiological action only, but applies likewise to many of its purely chemical and physical properties. So much so, indeed, is this the case that its exceptional physiological character might have been foreseen.

7. *The toxic action of a series of comparable salts runs parallel with the solubility in such a way that as the solubility increases the toxic action either increases likewise or else diminishes.*

8. *When the quantity of salt present in Koch's jelly is less than the minimum dose required to prevent the development of micro-organisms, the number of colonies which develops increases as the amount of salt diminishes, but as a rule much more rapidly.*

[1] As represented in terms of either the minimum toxic weight of metal or of the minimum molecular toxic dose. The minimum molecular toxic dose = minimum toxic weight of salt ÷ molecular weight of the salt.

9. When Koch's jelly has been previously neutralized with sodium carbonate the minimum quantity of metallic salt required to prevent the development of aërial micro-organisms is scarcely altered in the case of KCl, NaCl, $MgCl_2$, and $HgCl_2$, but is slightly greater in that of $CaCl_2$, and much less in the case of KBr, KI, NaBr, NaI, $ZnCl_2$, and $CdCl_2$, than when the jelly has not been neutralized.

10. *Mercuric iodide*, notwithstanding its comparative insolubility, *has an exceptionally high antiseptic power*, which is 1½ times as great as that of mercuric chloride per weight of salt, or 2½ times as great per weight of metal, or 3 times as great per minimum molecular toxic dose.

Geological Society, November 20.—Mr. W. T. Blanford, F.R.S., President, in the chair.—The Secretary announced that a series of specimens from the line and the neighbourhood of the Main Reef, east and west of Johannesburg, Witwatersrand Gold Fields, had been presented to the Museum by Dr. H. Exton, and a letter from that gentleman in explanation of them was read. In this Dr. Exton stated that all but one of the mines represented were on the main reef of the district, which has a general direction east and west, its dip varying generally from 45° to 80°. South of the main reef, and parallel to it at a distance of 15–20 feet, is a narrow reef known to the miners as the "south leader," and generally much richer than the main reef. The gold-bearing deposits consist of conglomerates, specimens of which, and of a purplish-red rock which forms a jagged ridge at some distance north of and parallel to the so-called reef, were contained in the collection. The President considered the occurrence of the gold in large quantities in such a conglomerate was a remarkable and interesting case. The rock was an ancient-looking one, and the country appeared to have undergone much disturbance. Dr. Hinde remarked that in Nova Scotia beds of conglomerate of supposed Carboniferous age were formerly worked for gold, but the yield had not been very great.—The following communications were read:—On the occurrence of the striped hyæna in the Tertiary of the Val d'Arno, by R. Lydekker.—The catastrophe of Kantzorik, Armenia, by Mons. F. M. Corpi; communicated by W. H. Hudleston, F.R.S. Secretary. The village is 60 km. from Erzeroum, and 1600 metres above sea-level. Subterranean noises and the failure of the springs had given warning, and on August 2 last part of the "eastern mountain" burst open, when the village, with 136 of its inhabitants, was buried in a muddy mass. The author described the district as formed of Triassic, Jurassic, and Cretaceous strata, subsequently broken up and torn by granitic, trachytic, and basaltic rocks, which overlie the Secondary rocks, according to the nature of the dislocation. The flow was found to have a length from east to west of 7–8 km., with a width ranging from 100 to 300 metres, and the contents were estimated at 50,000,000 cubic metres. It appeared as a mass of blue-grey marly mud, which, after the escape of the gases, solidified at the top; the inequalities projected to the extent of 10 metres. The site of the village was marked by an elevation of the muddy mass, some of the *débris* of the houses having been carried forward. The lower part of the flow was still in a state of motion, and carried forward balls of marly matter. It was difficult to approach the source of this flow on account of the crevasses in the side of the mountain. An enormous breach served as the orifice for the issue of the mud, which emitted, it was said, a strong odour. The violent projection of this marly liquid and "incandescent" (?) mass had carried away a considerable portion of the flanks of the mountain, whose *débris* might be recognized on the surface of the flow by the difference of colour. Great falls were still taking place, throwing up a fine powder which rose into the air like bands of smoke. There were also fissures and depressions of the ground at other localities in the neighbourhood. The President, in commenting on the remarkable nature of the phenomenon, said it was not a volcanc eruption, but more of the nature of a mud-flow produced by a big landslip—possibly connected with the stoppage of the springs. Still it was on a very large scale, though clearly the effect of water and not of fire. Dr. Evans agreed with the President. It was difficult to reconcile the alleged incandescence with the other phenomena. Infiltration of water probably had something to do with the outburst. It was not even a mud volcano. The falling in of the mountain, he thought, might have been due to soft beds covered by harder material having oozed out. It would be interesting to know if there had been an increased rainfall prior to the occurrence. There was nothing of a truly volcanic nature mentioned in the paper. He should like to have further information about the incandescence. Mr. Dallas (the translator of the paper) said that the "redness" was reported by the people to the author. Rev. Edwin Hill thought that the mud-balls could in no way be explained by igneous agency. The photographs gave no indication of the presence of steam. As a landslip the amount was very great, and possibly the phenomenon might be something similar to the overflow of peat-bogs. Mr. Hudleston recalled the statement of the author regarding the geological constitution of the district, where masses of Secondary rocks are folded within igneous ones, probably of Tertiary age. It was likely, therefore, that some of the softer Secondary marls, pressed in more than one direction by harder rocks and soaked by water, might at last have given way. The immediate cause of the catastrophe could scarcely be indicated without a knowledge of the district. Such events occurred from time to time elsewhere. The Russian topographers, if his memory served him right, had described the bursting of a mountain-side with fatal results, in one of the valleys near Lake Issyk Kul. The smoke-like powder, resulting from the continued falls of rock, had often given rise to the notion of volcanic action. There could be no better instance of this than the case of Mount St. Elias, the highest mountain in North America. In geography-books this mountain has almost invariably been described as a volcano, and a portion has actually been designated as the crater. This illusion had been occasioned by the dust of rock-falls resembling smoke. We might well pardon the author for speculating on the probability of a return to volcanic activity in a region which bears so many traces of it as this part of Armenia.—On a new genus of Siliceous sponges from the Lower Calcareous Grit of Yorkshire, by Dr. G. J. Hinde.

December 4.—Mr. W. T. Blanford, F.R.S., President, in the chair.—The President stated that a circular letter had been received from the Secretary of the Committee on Geological Photographs, formed at the last meeting of the British Association for the Advancement of Science, to arrange for the collection, preservation, and systematic registration of photographs of geological interest in the United Kingdom, in which the aid and co-operation of geologists is earnestly requested. Copies of instructions, &c., drawn up in order to secure uniformity, are to be obtained on application to Mr. O. W. Jeffs, Secretary to the Committee, 12 Queen's Road, Rock Ferry, Cheshire, and one would be suspended on the Society's notice-board.—The following communications were read:—On remains of small Sauropodous Dinosaurs from the Wealden, by R. Lydekker.—On a peculiar horn-like Dinosaurian bone from the Wealden, by R. Lydekker. Among a series of vertebrate remains sent from the Dorsetshire County Museum to the British Museum, there is an imperfect, stout, short, cone-like bone from the Wealden of Brook, Isle of Wight. It appears to present a close resemblance to the horn-cores of the Dinosaur described by Prof. Marsh as *Ceratops*. The author did not regard the specimen as affording conclusive evidence of the existence in the Wealden of a large Dinosaur furnished with horn-like projections on the skull like those of the American *Ceratops*, but suggested that such might really prove to be its true nature.—The igneous constituents of the Triassic breccias and conglomerates of South Devon, by R. N. Worth. The reading of this paper was followed by a discussion, in which the President, Prof. Bonney, Dr. Geikie, Dr. Hicks, Mr. Hudleston, Prof. Hughes, and Prof. Judd, took part.—Notes on the glaciation of parts of the valleys of the Jhelam and Sind Rivers in the Himalaya Mountains of Kashmir, by Captain A. W. Stiffe. After referring to the previous writings of Messrs. Lydekker, Theobald, and Wynne, and Colonel Godwin-Austen, the author gave an account of his observations made during a visit to Kashmir in 1885, which appeared to him to indicate signs of former glaciation on a most enormous scale. A transverse valley from the south joins the Sind valley at the plain of Sonamurg, and contains glaciers on its west side. These, the author stated, filled the valley at no remote period, and extended across the main Sind valley, where horseshoe-shaped moraines, many hundred feet high, occurred, and dammed the river, forming a lake of which the Sonamurg plain was the result. The mountains which originated the above glaciers were described as being cut through by the Sind river, and the rocks of the gorge were observed to be striated, whilst rocks with a *moutonnée* appearance extended to a height of about 2000 feet. The whole of the Sind valley was stated to be characterized by a succession of moraines through which the river had cut gorges, whilst the

hillsides were seen to be comparatively rounded to heights of 2000 feet or more. The author had also formed the opinion that at Bâramulla the barrier of a former lake occupying the Kashmir valley was partly morainic, before reading Prof. Leith Adams's view of the glacial origin of some of the gravels of this point. The whole valley of the Jhelam from this point to Mozufferabad showed extensive glacial deposits, which had been modified by denudation and by the superposition of detrital fans, widely different in character from the glacial deposits. Below Rampoor the valley was thickly strewn with enormous granite blocks resting upon gneiss, and the author believed that they had been transported by ice. In conclusion, it was noted that the existing torrential stream had further excavated the valley since Glacial times, and, in places, to a considerable depth. Comments on this paper were offered by the President, Mr. Lydekker, General MacMahon, and Prof. Hughes.

Entomological Society, December 4.—The Right Hon. Lord Walsingham, F.R.S., President, in the chair.—Prof. Franz Klapálek, of Prague, was elected a Fellow.—Mr. W. L. Distant exhibited, on behalf of Mr. Lionel de Nicéville, a branch of a walnut tree on which was a mass of eggs laid by a butterfly belonging to the *Lycænidæ*. He also exhibited two specimens of this butterfly which Mr. de Nicéville had referred to a new genus and described as *Chætoprocta odata*. The species was said to occur only in the mountainous districts of North-West India, at elevations of from 5000 to 10,000 feet above the sea-level.—Dr. D. Sharp exhibited the eggs of *Piezosternum subulatum*, Thunb., a bug from South America. These eggs were taken from the interior of a specimen which had been allowed to putrefy before being mounted. Although the body of the parent had completely rotted away, the eggs were in a perfect state of preservation, and the cellular condition of the yelk was very conspicuous.—Mr. J. H. Leech exhibited a large number of Lepidoptera recently collected for him by Mr. Pratt in the neighbourhood of Ichang, Central China. The collection included about fifty-four new species of butterflies and thirty-five new species of moths. Captain Elwes observed that he noticed only two genera in this collection which did not occur at Sikkim, and that the similarity of the insect fauna of the two regions was very remarkable; about fifteen years ago, in a paper "On the Birds of Asia," he had called attention to the similarity of species inhabiting the mountain ranges of India, China, and Java. Mr. McLachlan, F.R.S., remarked that he had lately received a species of dragonfly from Simla which had previously only been recorded from Pekin. Mr. Distant said he had lately had a species of *Cicada* from Hong Kong, which had hitherto been supposed to be confined to Java.—Mr. W. H. B. Fletcher exhibited a preserved specimen of a variety of the larva of *Sphinx ligustri*, taken in a wood near Arundel, Sussex. Mr. W. White exhibited drawings of the larvæ of this species, and called especial attention to one of a variety that had been exhibited at a previous meeting by Lord Walsingham.—Mr. F. D. Godman, F.R.S., read a letter from Mr. Herbert Smith, containing an account of the Hymenoptera, Diptera, Hemiptera, and Coleoptera, he had recently collected in St. Vincent, where he was employed under the direction of a Committee of the Royal Society, appointed to investigate the natural history of the West Indies. A discussion followed, in which Dr. Sharp, Captain Elwes, Lord Walsingham, and Mr. McLachlan took part.—Captain Elwes read a letter from Mr. Doherty, in which the writer described his experiences in collecting insects in the Naga Hills, by means of light and "sugar." Colonel Swinhoe said that the attractive power of light depended very much on its intensity, and on the height of the light above the ground. By means of the electric light in Bombay he had collected more than 300 specimens of *Sphingidæ* in one night. Mr. J. J. Walker, R.N., stated that he had found the electric light very attractive to insects in Panama. Dr. Sharp, Mr. Leech, Captain Elwes, the Rev. Canon Fowler, and others continued the discussion.—Mr. de Nicéville communicated a paper entitled "Notes on a New Genus of *Lycænidæ*."—Mr. F. Merrifield read a paper entitled "Systematic Temperature Experiments on some Lepidoptera in all their Stages," and exhibited a number of specimens in illustration of his paper. The author stated that the darkness of colour and the markings in *Ennomos autumnaria* resulted from the pupæ being subjected to a very low temperature. In the case of *Selenia illustraria*, exposing the pupæ to a low temperature had not only affected the colour of the imagos, but had altered the markings in a striking manner. Lord Walsingham observed that it appeared that exposure to cold in the pupa-state produced darker colouring in the imago, and that forcing in that stage had an opposite effect; that insects subjected to glacial conditions probably derive some advantage from the development of dark or suffused colouring, and that this advantage was, in all probability, the more rapid absorption of heat. He said he believed that an hereditary tendency in favour of darker forms was established under glacial conditions, and that this would account for the prevalence of melanic forms in northern latitudes and at high elevations. Captain Elwes, Mr. Jenner Weir, and Dr. Sharp continued the discussion.

Linnean Society, December 5.—Mr. J. G. Baker, Vice-President, in the chair.—Mr. George Murray exhibited and made some remarks upon specimens of *Struvea macrophylla* and *S. plumosa*.—Mr. A. W. Bennett communicated some observations on a new and a little-known British fresh-water Algæ—*Schizothrix anglica* and *Sphæroplæa annulina*. It was pointed out that *Schizothrix* of Harvey's "Phycologia Britannica" is really an *Inactis*.—Mr. E. M. Holmes exhibited, as a new British marine Alga, a specimen of *Gracilaria divergens*, a rare native of the warmer portions of the Atlantic and the Mediterranean, which had been recently found at Brighton by Mr. J. Myles. The specimen exhibited possessed tetrasporic and cystocarpic fruits not described by Agardh.—Mr. Pascoe exhibited (with a view of eliciting information as to the *modus operandi*) a number of Crustacea and certain shells of the genus *Phorus* having various foreign substances attached to them. Commenting upon these specimens, Prof. Stewart gave an interesting account from personal observation of the way in which certain Crustacea collect and adorn themselves with fragments of shell, seaweed, &c., apparently as a protective covering.—Mr. T. Christy exhibited and made remarks on some "liquid-amber" or resin (*Attingia excelsa*) from Cochin China.—A paper was then read by Mr. George Massee on the life-history of a stipitate fresh-water Alga, illustrated by some excellent diagrams. A discussion followed, in which the chairman, Mr. Murray, and Mr. Bennett took part.—In the absence of the author, Mr. Harting detailed the chief points of interest in a paper by Mr. George Sim on the anatomy of the sand grouse (*Syrrhaptes paradoxus*), and the habits of this bird as observed on the sand hills of the coast of Aberdeenshire. A comparison was made of the sternum and the alimentary organs with the same parts in the pigeon and red grouse.

Chemical Society, December 5.—Dr. W. J. Russell, F.R.S., in the chair.—The following papers were read:—Compounds of phenanthraquinone with metallic salts, by Prof. F. R. Japp, F.R.S., and Mr. A. E. Turner. The authors have obtained several double compounds of phenanthraquinone with metallic salts, viz. $C_{14}H_8O_2$, $ZnCl_2$, crystallizing in dark, reddish-brown needles; $(C_{14}H_8O_2)_2$, $HgCl_2$, crystallizing in red, obliquely truncated prisms; and $(C_{14}H_8O_2)_2$, $Hg(CN)_2$, crystallizing also in red forms. They have prepared a similar compound from mercuric chloride and β-naphthaquinone, but could not obtain double compounds from benzoquinone, α-naphthaquinone, anthraquinone, diacetyl, or benzil. It would, therefore, appear that compounds of this class are derivable only from orthoquinones, and not from paraquinones or open-chain α-diketones. The intense colour of the double compounds indicates that in them the quinone preserves its distinctive character. In this respect they differ from the colourless compounds of the orthoquinones with sodium hydrogen sulphite, which, inasmuch as their formation involves reduction, are to be regarded as quinol derivatives.—Action of aldehydes and ammonia on α-diketones, by Mr. G. H. Wadsworth.—Phenylhexamethylene derivatives, by Dr. F. S. Kipping and Prof. W. H. Perkin.—Diphenylfurfuran, by Prof. W. H. Perkin and Dr. A. Schloesser.

Royal Microscopical Society, November 13.—Dr. C. T. Hudson, F.R.S., President, in the chair.—The Rev. Armstrong Hall exhibited a Bacillus from urine, which closely resembled *B. tuberculosis*.—Mr. Hardy exhibited and described a little apparatus which he had devised for the purpose of photographing an object under the microscope, without having to alter the position of the instrument in any way. He had originally made it in metal, but had found it too heavy; the one now before them was made of wood, and weighed about one ounce, the cost being nothing at all beyond the trouble of making it.—Mr. Watson exhibited and described a new pattern microscope for students (the "Edinburgh student's microscope"), and a student's petro-

logical microscope made upon the same lines; also, a small box for holding slides, for which a patent had been obtained by Mr. Moseley, its inventor. The slides were held in flat trays in the usual way, but they were so arranged that, upon opening the front of the box, the trays were drawn forward so as to form a series of layers overlapping sufficiently to expose the labels at the front end of each row, and enabling the position of any particular slide to be seen without the necessity of removing the trays in search of it.—Mr. Crisp exhibited apparatus by which it was proposed to convert a microscope into a microtome by placing the embedded substance in the lower end of the tube, and cutting sections by means of a blade fitted to move upon the stage plate.—Mr. J. Mayall, Jun., described the various microscopes and accessories which he had examined at the Paris Exhibition, pointing out that, whereas at former International Exhibitions most of the best makers in England, America, and other countries were exhibitors, on this occasion they had been rather conspicuous by their absence. The French opticians were fairly well represented as to numbers, but the instruments they exhibited were for the most part of the old, not to say antiquated, types. He had seen very little that was new in the matter of design.

Zoological Society, December 3.—Mr. Osbert Salvin, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of November 1889.—An extract was read from a letter received from the Rev. G. H. R. Fisk, concerning some specimens of *Bipalium kewense*, which he was keeping in captivity at Cape Town.—Mr. Henry Seebohm exhibited and made remarks upon some specimens of new or rare species of birds lately received from the Bonin Islands, North Pacific.—Mr. Sclater exhibited and made remarks on an egg of the crested screamer (*Chauna chavaria*), from the collection of Mr. J. J. Dalgleish.—Mr. F. E. Beddard read the first of a series of contributions to the anatomy of Picarian birds. The present communication treated of some points in the structure of the hornbills (*Bucerotidæ*), particularly of the syrinx, and of the muscular anatomy of these birds.—Mr. Beddard also read a paper upon the anatomy of Burmeister's cariama (*Chunga burmeisteri*), and pointed out the differences between this form and *Cariama cristata*.—Mr. G. W. Butler read a paper on the relations of the fat-bodies (subperitoneal and subcutaneous) of the Sauropsida. The author showed that a consideration of the subperitoneal fat-bodies appeared to throw light on the condition of the abdominal membranes in the monitors.—A communication was read from the Rev. H. S. Gorham, containing descriptions of new species of the Coleopterous family Erotylidæ from various localities.—A communication was read from Mr. L. Taczanowski, containing the description of a new warbler of the genus *Locustella* from Corea, which he proposed to call *Locustella pleskei*.—Mr. Oldfield Thomas pointed out the characters of a new mungoose, allied to *Herpestes albicaudatus*, which he proposed to call *H. grandis*. The type specimen (a skeleton) had been obtained by Mr. T. E. Buckley in South-East Africa.

STOCKHOLM.

Royal Academy of Sciences, December 11.—The Ascoceratidæ and the Lituitidæ of the Upper Silurian formation of Gotland described, by Prof. G. Lindström.—Researches on the constitution of the spectra of emission of the chemical elements, by Dr. T. R. Rydberg.—On the observations at the Observatory of Upsala to determine the equinoctium of the spring 1889, by Dr. K. Bohlin and C. Schulz-Steinheil.—Definitive elements of the orbit of the comet 1840, by C. Schulz-Steinheil.—On the ores and minerals of the Gellivard district, especially the apatite, by Herr A. Sjögren.—The English edition of the atlas of fac-simile maps, by Prof. A. E. Nordenskiöld, exhibited by himself.—On the conductibility of snow, by Dr. S. Hjältström.—On the influence of the averting force of the telluric rotation on the movement of the air, by Dr. N. Ekholm.—A large collection of mosses from Japan, Korea, and East India, presented to the State Museum by Captain S. Ankarcrona, R.N., and determined by Dr. W. Brotherus, of Helsingfors, and by Dr. Carl Müller, in Halle, exhibited by Prof. Wittrock. On the recently-published first part of the second supplement to C. F. Nyman's "Conspectus floræ Europeæ," by Prof. Wittrock.—Echinologica, by Prof. S. Lovèn.—Some morphologic researches on the arteries of the brain of the Vertebrata, by Herr A. Klinkowström.—Derivatives of ortho-amido-benzyl alcohol, ii., by Dr. G. H. Söderbaum and Prof. Widman.—On distri azol combinations, by Dr. Bladin.—On naphtoe acids, by Dr. Ekstrand.—Derivatives of sulphate of ammonium, by Herr O. S. Hector.—Demonstration of some theories of Poincaré, by Herr de Brun.

THE BERMUDA ISLANDS.

A Contribution to the Physical History and Zoology of the Somers Archipelago. With an Examination of the Structure of Coral Reefs. By Angelo Heilprin, Curator-in-Charge and Professor of Invertebrate Palæontology at the Academy of Natural Sciences of Philadelphia, &c. With additions by Prof. J. P. McMurrich, Mr. H. A. Pilsbry, Dr. George Marx, Dr. P. R. Uhler, and Mr. C. H. Bollman. (Philadelphia: Published by the Author, 1889.)

THIS work is mainly the outcome of researches concerning the physical history, geology, and zoology of the Bermudas, which were accomplished under the auspices of the Academy of Natural Sciences of Philadelphia in the summer of 1888. The author's principal object was to satisfy his own mind on certain points connected with the structure of coral reefs, and but little zoological work was contemplated. Fortunately, however, the collection of zoological material proved more extensive than was expected, and in this respect Prof. Heilprin was greatly assisted by the students who accompanied him.

After a pleasant chapter of "general impressions," the author gives the results of his examination of these islands, and then proceeds to make such a vigorous attack on the views advanced by Agassiz, Murray, and their followers, concerning the origin of coral islands, that those attacked may be pardoned if they regard him as an apostle of the old belief.

Coming from the pen of Prof. Heilprin, this volume will, however, be welcomed by both sides in the controversy, but he must expect from his opponents an energetic reply to some of his criticisms, and an unmistakable dissent from some of his conclusions. Thus when the author asserts that the existence of an atoll in the present position of the Bermudas is not demonstrable, and that we have yet to learn to what form of coral structure these islands belong, he is at variance with most other authorities on the subject; and it becomes at the same time a little difficult to follow him in his conclusion that the results of his researches go to sustain the atoll-theory of Darwin. However, laying this difficulty aside, and accepting the fact, fairly established in this volume, that these islands have undergone recent movements, first of upheaval and then of subsidence, we may ask: "Of what use is this double testimony to any theory, whether of upheaval or of subsidence, unless a direct connection is first established between the form of a reef and the character of the movement?" The direct testimony of a single atoll that can be proved to have grown in a stationary area will, unless this connection be established, far outweigh the presumptive evidence derived from a slight subsidence of every atoll in the Indian and Pacific Oceans.

Dr. Rein, in the instance of the Bermudas, was the leader of one of the early skirmishes in this controversy, and it was to his description of these islands that the opponents of the atoll-theory of Darwin pointed in support of their views. They miss, therefore, in this book, any special exposition on the author's part of the relation of his own views to those of Dr. Rein. They also will fail to see how Murray's explanation of the origin of the inner basins of the Bermudas by solution can be met merely by a statement of contrary conviction unsupported by experimental proof. Nor will they agree with Prof. Heilprin's assertion that the recent memoir of Agassiz on the Hawaiian Islands can scarcely be said to contribute materially towards the solving of the problem.

The author in this volume treats as absurd my attempt to show that a true conception of the relative dimensions of an atoll is necessary to understand the nature of the problem. I was aware that, if my meaning was not understood, I should lay myself open to some curious reflections, and therefore the point is further elucidated in my description of the Keeling Islands, in the *Scottish Geographical Magazine.* To Prof. Heilprin's inquiry as to how near are we brought to an understanding of the character of an atoll by a true conception of its relative dimensions, I would answer with the query, "How far are we misled from the truth by the woefully-distorted sections of atolls that are employed by lecturers and by the authors of text-books?" Let me cite a single instance—that of Darwin's section of the Great Chagos Bank, which gives that atoll (which is 76 miles in width and 40 to 50 fathoms deep) the relative dimensions of a soup-plate. Some go further, and draw, with a free hand, a deep, saucer-shaped section of such reefs. Illustrations of this kind practically beg the question at the start, if we are arguing in favour of the theory of subsidence. The mind is at once informed by the eye that there is a deep basin to be accounted for, whereas a section on a true scale would exhibit no appreciable depression. In the exaggeration of the relative depth of an atoll is concerned the very essence of the problem, and a side-note cannot remove the impression made by a false section on the mind. Our conception of the problem can scarcely be assisted by a section of an atoll representing in the lagoon greater oceanic depths than the *Challenger* ever plumbed.

Passing from these controversial matters to the zoological section of this volume, we find a very interesting chapter on the relationship of the Bermudian fauna. The number of known species of marine Mollusca has been increased from 80 to about 170, none of the eleven species peculiar to Bermuda having been described before this exploration. Strangely enough, though "overwhelmingly Antillean in character," the marine Mollusca include a Pacific element. The land mollusks have been increased from about twenty to thirty species, of which eight appear to be confined to these islands; but, in explaining the mode of transport of the non-peculiar species, the author scarcely seems to have laid sufficient importance on the transporting agencies of commerce. A remarkable fact noted in connection with the Bermudian crustaceans is the occurrence of three macrurans—*Palæmonella tenuipes*, *Palæmon affinis*, and *Penæus velutinus*—hitherto only recorded from the Pacific. Prof. Heilprin arrives at some interesting conclusions in this chapter, and perhaps the most important one is connected with the large proportion of peculiar forms amongst the land-shells, a circumstance which is pointed to as evidence not only of the antiquity of a portion of

the fauna, but also of its derivation from some pre-existing fauna in those islands. Much other zoological matter is to be found in this volume, though only a portion of the collections are here described. We are informed, however, that a great deal of systematic work still remains for the naturalist in the Bermudas, and Dr. Uhler, in respect of the insects, avers that much arduous collecting, particularly of the less conspicuous kinds, is still needed.

I do not know whether any argument for the considerable antiquity of the Bermudas from the character of the fauna has been advanced before. At all events, Prof. Heilprin's valuable suggestion opens up a line of inquiry in the case of coral islands generally, which might be pursued with profit. From investigations of the coral phenomena alone, I arrived at the conclusion that Keeling Atoll has a life-history of from 15,000 to 20,000 years, and that it is now in the last quarter of its existence. If this coral island is a type, then atolls must possess a high antiquity; and, taking our cue from Prof. Heilprin, we may ask whether, in the fauna and flora of a typical Pacific or Indian Ocean atoll, there is anything to suggest that they are derived from a pre-existing order of things. Confining ourselves to the flora, we find that oceanic atolls are mostly characterized by Hemsley as possessing no endemic element amongst their plants. Yet some of these large atolls must have once engirt, according to the theory of subsidence, a mountainous island possessing an upland flora, and, as in the case of the Fijis, not a few peculiar species. The islands formed on the encircling reef, just like the coral islands that often front the shore of a mountainous island in the Western Pacific, would possess, in addition to the common littoral plants, a number of plants derived from the slopes of the adjacent island. How comes it, then, that, if these large groups of oceanic atolls mark the disappearance of mountain-ranges, we find no sign of the vanished upland flora amongst the common littoral plants that are now brought by currents, winds, and sea-birds to every atoll? The Island of Tahiti could hardly disappear beneath the ocean without leaving a Tahitian impress on the flora of the surviving atoll. A similar reflection often occurred to me whilst on the Keeling Islands.

In conclusion, I would remark that partisanship in matters of scientific dispute cannot affect the value of this work by an American naturalist on one of the oldest of British possessions. The book is illustrated with several beautiful phototypes of general views in the islands, as well as of the æolian formations and of the coast scenery; and seventeen lithographic plates accompany the zoological descriptions. H. B. GUPPY.

THE USEFUL PLANTS OF AUSTRALIA.

The Useful Plants of Australia (including Tasmania). By J. H. Maiden, F.L.S., F.C.S., &c. (London: Trübner and Co. Sydney: Turner and Henderson. 1889.)

ALTHOUGH designed in the first instance as a hand-book to the specimens in the Technological Museum at Sydney, this work in its present form is really a concise text-book treating of "all Australian plants which, up to the present, are known to be of economic value, or injurious to man and domestic animals."

The literature of Australian economic botany may be said to date from the Great Exhibition of 1851. Owing, however, to the unsettled nomenclature of Australian plants previous to the publication of the great "Flora Australiensis," by Bentham and Mueller, the properties of the same plant were often found described under numerous botanical names. The publication of the "Flora," and the subsequent issue of Baron Mueller's "Census of Australian Plants" (with annual supplements), have now rendered species names easily accessible to workers in all parts of Australia, and the ground is well prepared for such a publication as that which lies before us. It is a bulky volume of 700 pages, well arranged, well got up, and furnished with an excellent index of botanical names, and also one of vernacular names. As Mr. Maiden reminds us, this is the first attempt made to grapple with the economical botany of Australia. He has wisely followed Baron Mueller in all essential details of classification, and due credit is given throughout the book to this learned and indefatigable worker, now, the greatest living authority on all that relates to Australian vegetable life. The arrangement of subjects has been adopted as that found most convenient in the Museum. This is not, perhaps, the best arrangement for a text-book, as it involves considerable repetition of names and synonyms under each section; but on that point we are not disposed to quarrel with the author. It opens, with human foods, and food adjuncts; and these are succeeded by forage plants, drugs, gums, resins and kinos, oils, perfumes, dyes, tans, timbers, fibres, and it closes with plants having miscellaneous uses not previously enumerated. A glance at the book shows very clearly, that if we except timbers, a description of which occupies about one-half the contents, the economic products of Australia are not of extraordinary importance. It is noticeable that the northern parts, where the flora is reinforced by representatives from the Malayan Archipelago and Southern Asia, yield most of the plants possessing medicinal properties. The genus Eucalyptus, comprising more than 130 species, yields excellent timber, kinos, and essential oils, and probably the chief economic products of Australia derived from native plants. Mr. Maiden has brought together practically all that is known about the industrial application of "gum"-trees, but we cannot now attempt to follow him.

Eucalyptus Gunnii (a large plant of which grows in the open air at Kew) yields a sweetish sap converted by settlers into an excellent cider. This, and manna, from *E. viminalis* and *E. dumosa* are probably the only food products derived from Eucalyptus trees. In the production of Eucalyptus oil (from *E. amygdalin* and *E. globulus*), Australia, it appears, has powerful competitors in Algeria and California, where gum-trees have been largely planted during the last twenty years. In the latter country, a large quantity is available as a by-product in the manufacture of anti-calcaire preparations for boilers.

The widely-spread Acacias of Australia, locally known as wattles, are hardly less useful than the gum-trees. Owing to the immense number destroyed for the sake of the bark used in tanning, the wattles in some districts are said to be threatened with extinction. Some whose leaves are eaten by stock are also becoming scarce. To counteract these influences, systematic attempts have been

made to plant wattles on a large scale. It is doubtful, however, whether, except in South Australia, such plantations will be ultimately successful. Gum arabic, of good quality, is yielded by various species of Acacia, but owing "to the great cost of unskilled labour in Australia, and the impossibility of utilizing the services of the aboriginals, it will never find its way into the world's market to any very great extent." Australian indigenous edible fruits, roots and leaves and stems, are apparently wisely left to the appreciation of "school-boys and aboriginals." Almost more important than food in a dry country is a constant supply of water. The aboriginal method of obtaining water from the fleshy roots of certain trees such as *Hakea leucoptera*, and from the stem of *Vitis hypoglauca*, is similar to that adopted in other countries, but Mr. Maiden has wisely given prominence to the fact, as the knowledge of it may be the means of saving the lives of many lost in the bush. Very few native Australian plants yield valuable fibres. The aboriginals appear to prepare their fishing-nets by chewing fibrous plants, and "this practice causes their teeth to be worn down to a dead level." In the same manner, we may add, the natives of Formosa prepare certain fibres for making clothes.

The best fodder grass of Australia is said to be *Anthistiria ciliata*, known as the "common kangaroo grass." There are several poison bushes (species of *Gastrolobium*, *Swainsonia*, and *Sarcostemma*) dangerous to stock so widely distributed as to render extensive tracts of country unoccupiable. These of late years have been reinforced by noxious weeds from other countries.

It is not to be supposed, however, that our knowledge of the economic uses of Australian plants is yet complete, and we are glad to learn that the author is actively engaged in observations that no doubt will be incorporated in a later edition. In the meantime, however, we cannot do better than commend this work as a most trustworthy guide in a handy form to the useful plants of Australia.

D. M.

MOUNT VESUVIUS.

Mount Vesuvius. A Descriptive, Historical, and Geological Account of the Volcano and its Surroundings. By J. Logan Lobley, F.G.S., &c. (London: Roper and Drowley, 1889.)

MANY people have been puzzled by the fact that there are so few English books on Vesuvius, especially of the descriptive type. The appearance of this work was looked forward to with ardent expectations, but it is doubtful whether it will fulfil them. Prof. Phillip's work was a remarkable one considering the short stay he made in Naples, but possessed those defects that all books must have which are written from little experience. Prof. Phillips wrote immediately after his visit. The first book of Prof. Lobley was prepared under similar circumstances, but apparently he has not re-examined the district for twenty years. Nearly every geologist on his visit to the type volcano of the world is attacked by a fever to write something about it—witness the 1300 or more books and articles in all languages referring to it—but a few months bring him safely through his complaint, and leave him satisfied that years of careful study on the spot will hardly qualify him to produce even a short description. This leads us to the main defects of the work, which spring from the author's want of personal observation, and the necessity of his obtaining information second-hand. Many recent authorities do not seem to have been consulted by Prof. Lobley. In consequence, he constantly makes statements that are incorrect or only partially accurate. Another fault to be found is the very incorrect and old-fashioned illustrations which would much bother a new-comer to the district with this work as a guide. Many of the crystal forms are incorrectly drawn, and in Plate xiv. dykes should not be represented as pipes branching out from the main chimney, but principally as radial sheets.

The accounts of the Phlegrean Fields, so far as they go, are very attractive, but lack that accuracy that a recent visit would have conferred. In describing Vesuvius, he mentions the library of vulcanology collected in the Naples section of the Italian Alpine Club, stating that 25,000 volumes are there preserved, which is more than three times the number. Neither will most people have had such a favourable experience of Vesuvian guides as Prof. Lobley. Yet altogether, the chapters on Vesuvius are the best part of the work, and are quite as much as a visitor with a couple of days to give to the mountain can comfortably absorb. The chapter on the geology of the volcano is clear and well written.

Unfortunately the book is spoiled—more perhaps than by anything else—by the author's views as to the causes of volcanic action. In the first place, the class of readers to whom the rest of the book appeals are not likely to possess sufficient physical and geological knowledge to be able to enter into the question, and to them chapter viii. is likely to prove a bore, and should they begin to peruse the book at this point, the effect will probably be that they will read no more. Even if it be supposed that the questions regarding the mechanics of the extrusion of igneous matter on the earth's surface are an easy matter of comprehension, the method of putting the subject into numbered paragraphs is much to be deprecated when the reader is not a specialist.

In the same way it is doubtful whether a description of rocks not occurring in the district is likely to be of use. Why mention the rare local rocks, "analcimite," "haüynophyre," "tholeite," &c., while "gabbro," "diorite," "syenite," are neglected?

The chapter on the minerals of Vesuvius is little more than a catalogue of every one that can possibly be raised to a species; some being obtained by dissolving saline crust in water, and allowing the solution to crystallize—a method that is hardly justifiable. Of far greater interest would have been a chapter on the general mode of occurrence, origin, &c., of the principal species, their characters being left to the systematic treatises on mineralogy.

The book is neatly got up and well-divided into separate chapters, so that the traveller, who will make most use of it, can easily turn up to a short account of any particular locality or subject. The language is clear, and not overburdened by petrological or other very learned words. Altogether, putting aside the above-mentioned blemishes, the work is likely to be of much use in leading travellers to observe for themselves one of the most interesting of geological phenomena.

OUR BOOK SHELF.

Index of British Plants, arranged according to the London Catalogue (Eighth Edition), including the Synonyms used by the Principal Authors, &c. By Robert Turnbull. Pp. 98. (London: George Bell and Son, 1889.)

THIS alphabetical synonymic list of British flowering-plants and vascular Cryptogamia is similar in general plan to that which was published about a year ago by Mr. Egerton-Warburton, which we noticed at the time of its issue (NATURE, vol. xl. p. 306). The author uses as a basis the last edition of the London Catalogue, and gives the synonyms of all the species that are described under different names in "English Botany," Bentham's "Handbook," Babington's "Manual," Hooker's "Student's Flora," "British Wild Flowers," Lindley's "Synopsis," Hooker and Arnott's "British Flora," Withering's "Arrangement," Notcutt's "Hand-book," and Hayward's "Pocket-book." The author has carried out his task very carefully, and has added an English name for each species, and given at the end a list of English names in alphabetical order. Two things lately have combined to cause considerable change in plant-names, the revision and redescription of the genera by Bentham and Hooker, and the increased attention which has been paid in tracing out priority by Mr. Daydon Jackson and Mr. Britten in England, and by Ascherson, Nyman, and many other writers on the Continent. We have noted a few slips in turning over the pages. For instance, there are only two native species of *Achillea*, not five—*decolorans*, *serrata*, and *tanacetifolia*, being manifest introductions. No wonder the author has not been able to refer some of the older bramble names to their London Catalogue synonyms. *Guntheri*, Bab., and *saltuum*, Foche, are both synonyms of the plant called *flexuosus* in the London Catalogue. The book will be found useful to many collecting botanists scattered up and down the country who have been puzzled to understand what was intended by many of the newly-introduced names. J. G. B.

Practical Observations on Agricultural Grasses and other Pasture Plants. By William Wilson, Jun. (London: Simpkin, Marshall, and Co., 1889.)

MR. WILSON tells us that "agriculturists have allowed themselves to run too much after a channel of indoor investigations." We do not know that this has been a fault in agriculturists, and are not convinced of the fact. Mr. Wilson appears to have omitted to acquire one important accomplishment in a writer on any subject—namely, the power of writing intelligibly. He tells us that "soil may be described as earthy matter on the surface of the globe"; that "climate has been described as a very complex matter, depending on a great variety of conditions"; but he does not say by whom it has been so lucidly "described." We are told that "sweet-scented vernal grass is one which most writers on grasses give a place as a useful grass, but not very definite as to what place it belongs, as it is not very readily eaten in some parts where there is a considerable quantity of it." Speaking of rough-stalked meadow-grass, he says:—"The Rev. J. Farquharson, F.R.S., mentions in his paper, which I have previously spoken of, as having cultivated it successfully on such soil, testifies as to the fondness of animals—both cattle and horses—for it, both as pasture and hay." Again, he informs us that "the fact has been pretty well borne out that a great fault has been to look at cultivation too much in the light of a matter which has been thoroughly investigated, when in reality it has little more than reached its infancy." Now, with all respect to Mr. Wilson, it appears to us to be mere cant to talk of the most ancient of all arts as having only reached its infancy. The style in which this little eighteen-penny book is written is poor and obscure, and the above quotations may be considered as fair samples of it. For instance, the eye falls by chance on the following passage (p. 70):—"The results of my observations have led me to the same conclusion as Mr. Sinclair—am of opinion that a mixture of it (*sic*) on dry soil would prove satisfactory, but should not be sown on clay moist soil." That this work should have reached a second edition is certainly strange, and appears to indicate that the agricultural palate is, as yet, particularly fresh. It must require a good deal of open-air exercise to enable a reader to digest Mr. Wilson's crudities.

W.

The State. Elements of Historical and Practical Politics By Woodrow Wilson, Ph.D., LL.D. (Boston, U.S.A.: Heath and Co., 1889.)

THIS work may be regarded partly as a text-book of political science adapted to the education of the young, partly as a repertory of what the writer calls "governmental facts," useful to readers of all ages. In the first part of his task Mr. Wilson has encountered great difficulties. He has no predecessors in whose steps to follow. Also the loose mass of facts and opinions which make up what is called political science does not admit of being compressed with safety. Again the class to whom Mr. Wilson offers a highly concentrated intellectual pabulum are little able to assimilate this species of nutriment even in its most digestible form. The young man, says Aristotle is not fit to be a student of political science. These difficulties appear to have been surmounted by Mr. Wilson better than might have been expected. He avoids the dogmatism to which short catechisms are liable. For instance in his section on the probable origin of government he does not rule that the earliest constitution of the family was patriarchal, or "matriarchal," as we believe it is now the fashion to say. While inclining to the former view he presents also the latter; and gives references by the aid of which the enquiry can be pursued. He stimulates curiosity and affords the means of gratifying it. The "evolution of government" is traced from the origin of the Aryan family through the changing types of Greek and Roman governments. This "institutional history" is somewhat dry; but the writer expects that the topical skeleton furnished by him will be clothed upon by the lessons of the intelligent teacher. Coming to modern times, we find a description of the principal pieces of political machinery which are now in use in the civilized world. This compilation seems to serve the purpose of a sort of magnified "Whittaker." If anyone who has not exhausted the subject of Home Rule wishes to refresh his memory as to the relations between Austria and Hungary or Sweden and Norway, he can here look out, as in a political dictionary, the main facts. We come nearest to the "practical politics" announced in the title in the chapter which discusses what are the proper objects of government. "This," says Mr. Wilson with much good sense, "is one of those difficult problems upon which it is possible for many sharply opposed views to be held apparently with almost equal weight of reason . . . It is a question which can be answered, if answered at all, only by aid of a broad and careful wisdom whose conclusions are based upon the widest possible inductions from the facts of political experience in all its phases." Mr. Wilson's solution of what Burke has called the "finest problem in legislation" is thus stated:—"It should be the end of government to *accomplish the objects of organized society*.... Not licence of interference on the part of government, only strength and adaptation of regulation. The regulation which I mean is not interference, it is the equalization of conditions, so far as is possible, in all branches of endeavour." Perhaps this teaching would have been more impressive if the writer, condescending to particulars, had discussed pretty fully any one question such as whether in any assigned country, the railways ought to be managed

by the state. Once more however we admit that the scope and limits of his work have imposed upon him almost insuperable difficulties.

Introductory Lessons in Quantitative Analysis. By John Mills and Barker North. (London: Chapman and Hall, 1889.)

THIS book of eighty-five pages is the first part of a larger work by the same authors, which will shortly be published. It is designed mainly for the use of "students in evening classes who have but little time to spare in acquiring such knowledge," and also to be of service for the Science and Art Department examination, as well as those of London University. The descriptions contained in the three chapters constituting the book, and which treat of preliminary operations, gravimetric analysis, and volumetric analysis, respectively, are meagre in the extreme, and lack many details essential to a primer. Slips and loose statements are numerous. For example, the student is led to infer that the ash of *any* of Schleicher and Schüll's filter-papers is negligible. Lead is estimated by means of "bichromate of potash," which is formulated as K_2CrO_4. On p. 62 the authors assert that "Normal solutions of *univalent* substances like iodine, silver nitrate, sodium chloride, &c., contain *their molecular* weight in grams in one litre." Whatever be the meaning attached to this, it is in no way confirmed by what follows on p. 63—namely, that "The *atomic* weight of iodine being 126·5, a normal solution would contain *this* number of grams in one litre."

The general scheme of work set out in the lessons is satisfactory, and if carefully elaborated might be useful. In its present condition, however, the effect of the book on the beginner cannot be other than confusing.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Note on a Probable Nervous Affection Observed in an Insect.

WHILST walking in the garden one bright September morning, my attention was called to a moth fluttering in a peculiar manner on the ground; it kept going round and round in a circle, running with its feet on the stones, its wings meanwhile being in rapid motion.

I captured the insect, which proved to be a quite fresh specimen of a male *Orgyia antiqua* (vapourer moth), of which there were many in the garden.

I replaced the insect without injury on the path, and watched it more closely.

The movements of the wings were irregular, convulsive, and very rapid in character; the feet and body were also in rapid movement, resulting in a circular motion of the whole insect from right to left—that is, in the same direction as the movements of the hands of a watch.

I again captured the insect, thinking that perhaps one of its antennæ might have been injured; but on careful examination with a hand lens, I could detect no lesion nor the presence of any parasite which might account for the condition.

I again placed the insect on the path, when it immediately began to rotate as before. It seemed unable to keep still, though evidently trying to do so.

Occasionally it would wedge itself in between two or more small stones, with its head downwards, and the under surface of its body upwards, its wings resting on the stones below; in this position it appeared to obtain some relief, as the movements were less continuous, though every breath of wind caused a convulsive twitching of the wings and body. On one occasion a leaf fell upon the insect whilst wedged in, causing a very violent convulsion of the whole insect, by which it was jerked quite out of its retreat, when the gyrating movements at once began again.

I tried stroking the antennæ with the point of a pencil, but this had no effect, nor could I obtain cessation of movement by stroking the body or the wings; on the contrary, when the insect was wedged in each touch caused a convulsion, varying with the intensity of the stimulus applied.

These movements continued without interruption for fully forty minutes, the insect gyrating in a space about a foot square. At the end of that time I placed it upon a piece of smooth paper, when the movements became more rapid and the gyrations less ample, it completing a turn in much less time than on the stones, owing, no doubt, to there being no projections on the paper to cause the insect to deviate.

I then placed it in a shallow cardboard box in the full sunlight, but protected from the wind. In this way the convulsive movements were less intense and less frequent; the insect, however, was often jerked over on to its back, then, after a struggle or two, would right itself, and begin to go round. When, however, it managed to press the top of its head against the side of the box, so that its antennæ were pressed between the head and the side of the box, all movement ceased till some external stimulus again set it in motion.

At the end of one hour the insect seemed quite exhausted, a strong stimulation being required to develop one convulsion.

On examination I found that it had worn away, in its movements, all its legs with the exception of the left hind leg, which was apparently pretty intact, and had broken both its wings on the right side, so that the greater part of them hung useless over its body.

After a few more violent convulsions, the upper wing of the right side was broken off, and the insect now began to revolve from left to right, owing, I suppose, to the movements of the left leg; the others being reduced to mere stumps would have little power of propelling the insect.

About twenty minutes later, during a convulsion, the right hind wing was broken off.

Shortly afterwards I noticed that the convulsive movements of the antennæ, which had been slight up to that time, were much increased; indeed, they were moving so rapidly as to have the appearance of two small black wings.

One hour and fifty-five minutes after I first noticed the insect all convulsions had ceased; no stimulus could excite any; the moth was dead.

Conclusion.—The insect, suffering from no apparent injury, and being attacked by no internal or external parasite, was, I believe, suffering from some nervous lesion. I was unfortunately unable to examine the insect microscopically to ascertain if the nervous centres exhibited any pathological characters.

E. W. CARLIER.

Does the Bulk of Ocean Water increase?

THE idea was, I think, suggested by myself, and has been referred to with approval by Mr. Jukes-Browne, that much of the water on the surface of the globe was originally occluded in the molten interior, and has been emitted by volcanic action in the course of ages. Mr. Mellard Reade argues against this, that the moon is covered with volcanic craters, and yet has no water on its surface, and that if the accumulation of surface water has followed volcanic action on the earth, it ought likewise to have done so on the moon. He concludes:—"At all events, it seems a reasonable question to ask why oceans should be supplied with water from the perspiring pores of mother earth, while her offspring, the moon, is so dry as to have absorbed into herself all evidence of any aqueous envelope that may have formerly existed."

It is a singular coincidence that one possible answer to this objection is suggested by a notice in the "Astronomical Column" of the same number of NATURE which contains Mr. Reade's letter. Therein Prof. Thury attributes apparent changes in the aspect of a lunar crater to the melting of snow or ice around it. Neither is he the only selenologist who thinks that those crater-rings consist more or less of frozen water. If they do so, then there *is* water on the moon, although in a solid state. On the other hand, Proctor, in his work on the moon, says that her

surface is more nearly black than white, which seems to render the existence of snow fields upon it less probable, unless they are covered with volcanic dust, as the end of a glacier usually is with rock *débris*.

But even if we take Mr. Reade's view, it is still conceivable that steam may have been the explosive agent in the moon's volcanoes, while her internal temperature was very high, and that the resulting water may have been subsequently absorbed after the body became cool, because the water would occupy less space within the interstices, which this theory of imbibition postulates, than the equivalent vapour did, when the temperature was high. The case of the earth would not be a parallel one, because it has not yet cooled.

Although not myself a selenologist, I have a suspicion that very little is known about the constitution of the moon; and that it is not even certain that its enormous craters are all of them really volcanic. It has been admitted by Prof. Darwin, in discussing the subject with Mr. Nolan, that on his view of the genesis of the moon it must have originally existed as a "flock of meteorites." These falling in during the later stages of the building up of its mass would have produced pits on a viscous surface, much like some of the craters.

At any rate it seems unsafe to rely upon arguments respecting the condition of the earth's interior, of which we know little, drawn from that of the moon's body, of which we know less.

Harlton, Cambridge. O. FISHER.

Exact Thermometry.

THE interesting experiments of Dr. Sydney Young, recorded in NATURE of December 19 (p. 152), seem to leave no doubt that the main part of the permanent ascent of the zero-point of a mecurial thermometer, after prolonged heating to a high temperature, is not due to compression of the bulb—rendered more plastic by the high temperature—by the external atmospheric pressure. Researches on the effects of stress on the physical properties of matter have convinced me that the molecules, not only of glass, but of all solids which have been heated to a temperature at all near their melting-point, are, immediately after cooling, in a state of constraint, and that this state can be more or less abolished by repeatedly heating the solid to a temperature not exceeding a certain limit, and then allowing it to cool again (it is not only the heating but the cooling also that is efficacious). It appears that the shifting backwards and forwards of the molecules, produced by this treatment, enables them to settle more readily into positions in which the elasticity is greatest and the potential energy is least.

This "accommodation" of the molecules, as Prof. G. Wiedemann and others have called it, is, as one might suppose, attended with alterations of the dimensions and other physical properties of solids, and is not confined to the release of molecular strain set up by thermal stress, but is extended to the strain set up by any stress whatever. As years roll on, the time of vibration of a metal pendulum gradually alters (and so, no doubt, do the lengths of our standard measures), the bulb of a thermometer diminishes in volume, a steel magnet parts with more or less of its magnetism, a coil of German-silver wire gains in electrical conductivity, &c. The changes in all these cases would probably be far less than they actually are if the temperature throughout the whole time could be maintained constant; but this last is not the case—heating and cooling goes on more or less every day. We may assist the effect of time by artificially increasing the range of temperature, but it would appear that we must not exceed a certain limit of temperature, which limit depends partly upon the nature of the substance and partly upon the stresses that are acting upon it at the time. Thus, the internal friction of a torsionally oscillating iron wire which has been previously well annealed may be enormously diminished by repeatedly raising the temperature to 100° C., keeping it there for several hours, and then allowing it to fall again. The amount of diminution of internal friction depends upon the nature of the wire, and on the load which there is at the end of it (if the load exceeds a certain amount, the friction is increased instead of diminished). In attempting to "accommodate" the molecules in this manner the heating must, at any rate in some cases, be prolonged for several hours, and the substance should then be allowed to remain cold for a still longer period.

I have not had much experience with glass, but I think it probable that the settling down of the zero-point of an ordinary thermometer into its ultimate position could be very materially facilitated by the heating and cooling process mentioned above.

HERBERT TOMLINSON.

36 Burghley Road, Highgate Road, December 23, 1889.

Self-luminous Clouds.

WITHOUT venturing to call in question the occasional occurrence of self-luminous clouds, I may be permitted to relate an observation which seems to reveal a possible source of error in the records of such phenomena.

On June 14, 1887, about 10.45 p.m., I witnessed an appearance over the north-north-west horizon which struck me as very remarkable. Amidst the strong glow of twilight a few fragments of cirrus cloud shone with a pure white light having so much the character of phosphorescence that it was difficult to believe the objects were not self-luminous. Looking out again an hour later, I found no trace of bright clouds, but in their place were small bands of cirrus showing dark and grey against the feeble twilight that remained. I could not but conclude that the clouds in both instances were the same or similar, lit up by the direct rays of the sun at the time of the first observation, and having lost his rays at the time of the second observation. Had they been self-luminous they should have become brighter instead of darker as the twilight faded.

It has been suggested to me that the bright clouds seen at 10.45 p.m. may have owed their brightness, not to the sun's rays falling on them at the time, but to a temporary phosphorescence, the result of exposure to the sun's rays in the day-time, and that this temporary quality had died out in the interval between the two observations.

I think this explanation is unnecessary for the following reasons. In the first place, it is certain that if a cirrus cloud were present in the atmosphere at a sufficient height to catch the sun's rays at 10.45 p.m. of a midsummer day, it would appear as a bright object amidst the surrounding gloom. And, secondly, there can be nothing incredible in the presence of a cirrus cloud at that height, when the persistence of twilight proves the presence of atmospheric particles of some kind at a greater elevation still.

GEORGE F. BURDER.

Clifton, December 19, 1889.

Duchayla's Proof.

I HAVE read with much interest the new proof given by Mr. W. E. Johnson of "the parallelogram of forces," in NATURE of December 19 (p. 153), and regard it as deserving a place among the best proofs that have been given.

I think, however, that, in his criticism of Duchayla's proof, Mr. Johnson runs to excess, when he says, "To base the fundamental principle of the equilibrium of a *particle* upon the transmissibility of force, and thus to introduce the conception of a *rigid body*, is certainly the reverse of logical procedure."

Duchayla's proof only requires us to suppose the transmission of force by *strings*. A particle is unthinkable. In presenting to a learner the conception of three equilibrating forces acting on a particle, we cannot do better than represent the forces by pulls in strings, and the particle itself by the knot where the three strings are tied together. All the steps of Duchayla's demonstration that the resultant force is directed along the diagonal of the parallelogram can be presented in tangible form with the aid of strings. I do not think this is an illogical or unnatural procedure.

Belfast, December 23, 1889.

The Satellite of Algol.

THE results of Vogel's photographs as to the satellite of Algol are of great interest to your astronomical readers. The observations made at Greenwich tended to the same result, but were unfortunately intermitted before anything approaching certainty was arrived at.

Regarding it as certain that the variations of Algol are due to the interposition of a satellite, the question of the slight change

in its period and the much larger change observed in the period of another variable of the same class in Cygnus becomes important. Besides the possibility of a third disturbing body it may be remarked that the existence of the solar corona and perhaps other appendages of the sun suggests that a resisting medium may exist in the entire space traversed by Algol and its satellite at each revolution. Also if the influence of gravitation is propagated in time (with whatever degree of velocity) the very rapid angular motion of a satellite which performs a complete revolution in less than three days (and in another variable of this class in twenty hours) could hardly fail to exhibit traces of this time-propagation. The attractive force, in fact, would never act in the line joining the centres of the principal star and satellite, and the deviation would probably be perceptible. I hope some mathematical astronomer will take up the problem, and show what the effects of each of these supposed causes would be. W. H. S. MONCK.

16 Earlsfort Terrace, Dublin, December 21, 1889.

Maltese Butterflies.

IN reading Mr. Wallace's "Darwinism" I am reminded by his observations on Island fauna (p. 106) of the impressions made upon me by the natural productions of Malta. My time was so fully occupied that I had little opportunity of exploring the country districts. I paid one visit to the extraordinary ruins of a Phœnician temple at Hagiar Kim, and one to the curious islet in St. Paul's Bay. On the latter I noticed several strange thistles and a beautiful flower—something like a large pink or purplish Tutsan. On the barren wastes round Hagiar Kim many familiar wild flowers grew, but all seemed shrunk and shrivelled as compared with those of Britain. The only unfamiliar one was called by the natives "the English flower." It was a tall trefoil with a drooping yellow trumpet-flower (not at all papilionaceous in form), and grew plentifully by the edges of the dustiest roads—unlike anything I know in England.

I lived for some time at the Imperial Hotel, at Sliema, which has a somewhat extensive garden, in which I used to spend about half an hour every morning. During April and May it was very lovely. The oleanders were then in their richest bloom; a shrub like a gigantic heliotrope, both in flower and leaf, was frequented by myriads of humming-bird moths; there were a few strawberry-plants, the fruit of which was delicious, although even smaller than that of our own wild kind; but most attractive to me were the clumps of valerian and scabious which were haunted, just as at home, by crowds of butterflies. These included blues, coppers, wood-ladies, painted-ladies, red-admirals, tortoise-shells, and swallow-tails. All of these were smaller than their English relatives are, and much less brilliant in colour. The swallow-tails were especially dwarfed in their proportions. I am puzzled to account for their presence in Malta, as there is nothing like a marsh or a fen in the whole island, whilst in England they are only to be found in the district of the meres. Can any of your readers throw light on this mystery? I saw several of the larger hawk-moths. They did not seem to suffer in size, but even they were dimmer in their colours.

Hoping to get a general idea of Maltese entomology, I visited the University Museum—only to find a few cases of insects in which every specimen had been devoured by mites!

GEORGE FRASER.

Leighside, Tunbridge Wells, December 22, 1889.

A Preservative.

I HAVE been very much troubled in conducting classes in mammalian anatomy by the want of a preservative medium which would retain the natural colour and texture of tissues, would impart to them no offensive smell, would be inexpensive, and easily handled. Various experiments with freezing, alcoholic, glycerine, and other media have all proven failures, and this fall I turned to experimentation upon the simplest and cheapest of all chemical reagents—water and table-salt. My entire success with these was so satisfactory that I shall, at the risk of telling an old story, state the experiments here.

I tried preserving squirrels in three strengths of salt solution, one of 5 parts by weight of salt to 95 of water, a second of 10 per cent. salt, and a third of 15 per cent. All gave satisfaction, but the 10 per cent. seems best, because the weakest solution in which putrefaction could not take place. Specimens placed in five times their bulk of this solution retain the natural flexibility of all the tissues; the peculiar look of nerve-tendon and blood-vessel against muscle is retained; the tint of muscle is faded somewhat by the solution of hæmoglobin from the blood, but it is still distinctly reddish; there is no putrefactive odour; all of this after four weeks standing in the laboratory.

This is so simple a preservative that I wonder that it is not in common use. H. LESLIE OSBORN.

Hamline University, St. Paul, Minnesota, December 7, 1889.

The Evolution of Sex.

IT is a fact well known to pigeon fanciers that the two eggs laid by pigeons almost invariably produce male and female. But no attempt appears to have been made to ascertain which of the two eggs produces the male, and which the female. The second egg is laid about twenty-four hours after the first. I have kept pigeons for seven or eight years, and have only met with one or two instances of the young birds, produced from the two eggs, being of the same sex. Recently I have made several experiments to ascertain if any relation exists between the order in which the eggs are laid and the sexes of the young birds produced. The results show that the egg first laid produces the female, the second egg the male. It may, perhaps, be well to give the experiments.

(i) Egg 1 of pair A produced a female; egg 2 was bad.
(ii) Egg 1 of pair B produced a female; egg 2 a male.
(iii) Egg 1 of pair B produced a female; egg 2 a male.
(iv) Egg 2 of pair B produced a male; egg 1 was bad.
(v) Egg 1 of pair C produced a female; egg 2 was bad.
(vi) Egg 2 of pair D produced a male; egg 1 was broken.

These experiments were made on white fantail shakers. A large number of experiments must be made to prove if this relation does exist; should it be found correct, an examination of the eggs and of the ovary of the parent might throw some light upon the "evolution of sex." M. S. PEMBREY.

Oxford, December 14, 1889.

Fighting for the Belt.

A FIGHT has been going on in my verandah for the last half-hour between two young birds—minas—with four birds of last season looking on.

Now the fight is just over. I have watched it throughout, and am positive that one of the on-lookers walked often round the combatants without interfering; and that another on-looker came, when he (or she?) could, and attacked one of the fighters. I say "came when he could," because the other on-looker prevented him if possible—even fighting to that end. It seemed to me very much as if two youngsters from different nests were fighting for the belt, and the parents looking on—the one complacently at her offspring's success, the other angry and breaking the rules of the ring to help the weaker. F. C. CONSTABLE.

Karachi, December 1, 1889.

The British Museum Reading-Room.

THE proper ventilation of this spacious room is a problem, surely not insoluble, but still awaiting solution. Is it not a serious grievance that to make use of one of the finest libraries in existence, means, for many, injury to health? Bad headaches and other ills, due to the stuffy and impure atmosphere which collects about the desks, are a common experience; and I know men who have given up going to the place on that account. For readers who live by work which can only be done there (some of whom are women), the matter is especially grave. Officials, again, will tell you that they often feel thoroughly done out after their day's work, which in itself is not generally severe. It seems to me the atmosphere improves after the lamps are lit; possibly owing to the upward current of heated air. If this were verified, it might offer a clue to improvement. The whole matter calls for thorough scientific investigation; and I would suggest, as a preliminary step, that analysis be made of the air (say) on a Saturday afternoon, with regard not only to its gaseous constituents, but also to micro-organisms, which are no doubt plentiful. A. B. M.

"AMONG CANNIBALS."[1]

IN the year 1880, Mr. Carl Lumholtz—as he explains in the preface to the work the title of which is given below—undertook an expedition to Australia, partly at the expense of the University of Christiania, with the object of making collections for the zoological and zootomical museums of the University, and of instituting researches into the customs and anthropology of the Australian aborigines. His travels occupied four years, and the first part of that time he spent in the south-eastern colonies, South Australia, Victoria, and New South Wales. From November 1880 to August 1881 he was in Central Queensland, and at the latter date he began his first journey of discovery, in the course of which he penetrated about 800 miles in Western Queensland—the results, he says, in no wise corresponding to the hardships he had to endure. He then went to Northern Queensland, where he spent fourteen months in constant travel and study, his head-quarters from August 1882 to July 1883 being in the valley of what he describes as "the short but comparatively broad and deep Herbert River," which flows into the Pacific at about 18° S. lat. From his base on this river he made expeditions in various directions, extending in some instances to nearly 100 miles, and he repeatedly came in contact with savages who had never before been visited by a white man.

It is to the period spent by him in the camps of the northern aborigines that Mr. Lumholtz chiefly devotes attention in the present volume, and it would hardly be possible to praise too highly the manner in which he has recorded his experiences. In every part of his narrative he displays a remarkable power of keen and accurate observation, and he presents his facts in a style at once so fresh and so simple that from beginning to end the reader's interest is maintained. Hitherto students of anthropology in Australia have derived their materials mainly from the southern part of the continent. Mr. Lumholtz may almost be said, therefore, to have broken new ground, and it is ground which it was well worth while to break, for the northern aborigines—from an anthropological point of view—are even more interesting than the southern tribes. They are decidedly at an earlier stage of development, and many of them have been only slightly and indirectly influenced by the ideas of European settlers.

If there are any survivors of the school of Rousseau, who attributed so many fine qualities to "the noble savage," it would be wholesome for them to study what Mr. Lumholtz has to tell about the savages of Northern Queensland. A more unlovely picture than his description of these poor people it would hardly be possible to imagine. He went to Australia full of sympathy with the natives; when he left it, he found that his interest in

FIG. 1.—Brow-band from Central Queensland (½ size).

them was as deep as ever, but that his sympathy had nearly vanished. That they are cannibals is beyond doubt. Luckily, they do not take to white flesh; it has too salt a flavour for their taste. But native flesh, when they can get it, provides them with the meal they like best, and they are quite willing to talk freely about the parts which they consider the most delicious morsels. They are not only treacherous, but seem to have not the faintest idea that treachery is anything to be ashamed of. If anyone is kind to them, they at once mistake his motive: they fancy that his generosity springs from fear, and if this notion gets into their minds, it is time for their benefactor to look about him, for they will not scruple to kill him in order to obtain possession of his goods. Mr. Lumholtz found that, when accompanied by a party of natives, it was unsafe for him to walk in front; he had always to bring up the rear, and to keep every one well in view. At night, before going to sleep in his tent, he had to fire his gun as a reminder that he had the means of defending himself. For this weapon they had the most profound respect; also for his revolver, "the baby of the gun." The supreme ambition of the native is to have as many wives as possible, their number being regarded as a test of his wealth and importance. And he takes good care that they shall not earn his approval too easily. All the hard, disagreeable work has to be done by women, and when they excite the displeasure of their lords they may think themselves well off if they are not severely beaten.

In every way these savages are creatures of impulse. It is difficult for them to fix their attention on anything, and they can look ahead only a very short way. Fortunately for themselves, they have no intoxicating stimulants, but tobacco gives them intense delight, and it was chiefly by promising to reward them with small quantities of it that Mr. Lumholtz was able to secure their services. When they have a chance, they gorge themselves with food; and on a hot day they plunge like dogs into water they may happen to pass. At the approach of night they become timid, trembling at every sound they hear in the bush; but with sunrise all their fears are dispelled, and after they have become thoroughly awake—a rather slow process—they are ready for any pleasure that may come in their way. It is a happy moment for them when they discover a tree in which there is honey. This they eat with rapture; and Mr. Lumholtz says he has known cases in which they have lived upon it for three days in succession. If a savage finds such a tree, and is not able at once to take possession of its treasure, he marks the tree, and the mark will be respected by members of his own family or clan. There is, however, no conception corresponding to the idea of property, so far as anything claimed by strangers is concerned.

[1] "Among Cannibals: an Account of Four Years' Travel in Australia, and of Camp Life with the Aborigines of Queensland." By Carl Lumholtz, M.A. With Maps, Coloured Plates, and 122 Illustrations. (London: John Murray, 1889.) We are indebted to the kindness of the publisher for the use of the cuts reproduced in this article.

As the people live in small groups, they have, of course, the germs of social life; but more than this they can scarcely be said to possess. But they have aptitudes which have been naturally developed in the circumstances

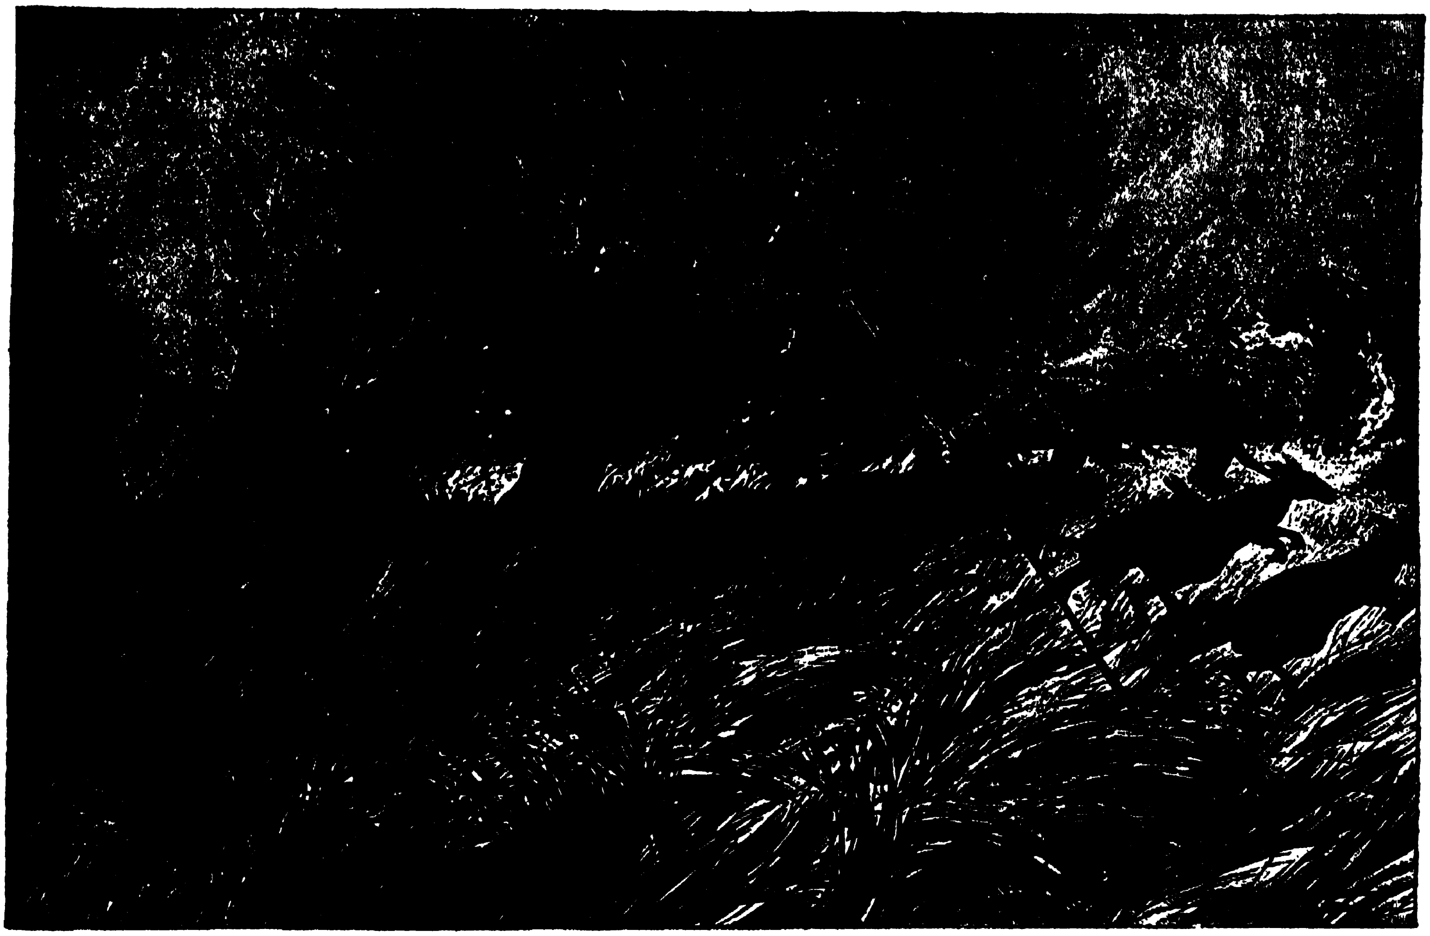

FIG. 2.—Wallaby Hunt.

in which they spend their lives. They display extraordinary cleverness in climbing trees, and their sense of

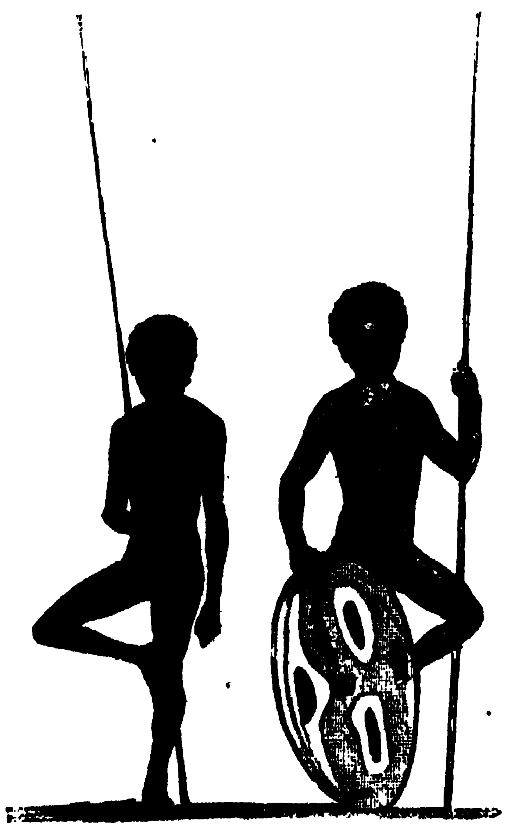

FIG. 3.—Peculiar position of natives resting.

smell is so keen that it is invaluable to them when they are tracking wild animals. In various kinds of handiwork they have considerable skill. Fig. 1 represents a brow-band of native workmanship (½ size). This specimen however, comes from Central Queensland. The Australians are generally supposed to throw the spear well, but Mr. Lumholtz never discovered any remarkable ability of this sort among the blacks of Herbert River. Fig. 2, represents a wallaby hunt, which he had an opportunity of seeing. He says:—

"Soon those who had remained behind spread themselves out, set fire to the grass simultaneously at different points, and then quickly joined the rest. The dry grass rapidly blazed up, tongues of fire licked the air, dense

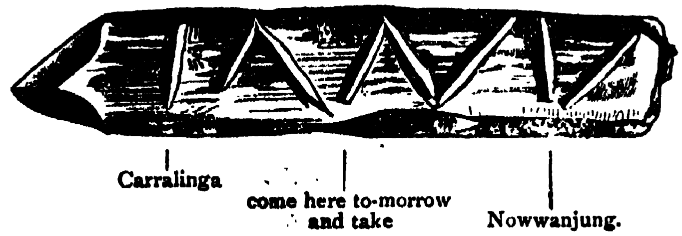

FIG. 4.—Message stick, with interpretation of inscription.

clouds of smoke rose, and the whole landscape was soon enveloped as in a fog. I fastened up my horse and went into this semi-darkness, watching the blacks, who ran about like shadows, casting their spears after the animals that fled from the flames. But though many spears whizzed through the air, and though a large field was burned, not a single wallaby was slain."

Mr. Lumholtz often noticed natives resting in a most peculiar position, represented in Fig. 3. "They stood on one foot, and placed the sole of the other on the inside of the thigh, a little above the knee. The whole person was easily supported by a spear." This custom is said to

prevail among the inhabitants of the Soudan and the White Nile district.

A kind of sign language is occasionally used by the Australians. It consists of figures scratched on "a message stick" made of wood, about four to seven inches long, and one inch wide. Fig. 4 represents one of these sticks. It conveys a message from a black woman named Nowwanjung to her husband Carralinga, of the Woongo tribe. "Other message sticks," says Mr. Lumholtz, "are engraved with straight or circular lines in regular patterns as in embroidery; this has caused an entirely different view of their significance, which supposes them to be merely cards to identify the messenger. This view may be correct, but it is not corroborated by my experience on Herbert River."

Mr. Lumholtz secured a valuable collection of zoological specimens, and some of the best passages in his book are those relating to this part of his work. Fig. 5 represents

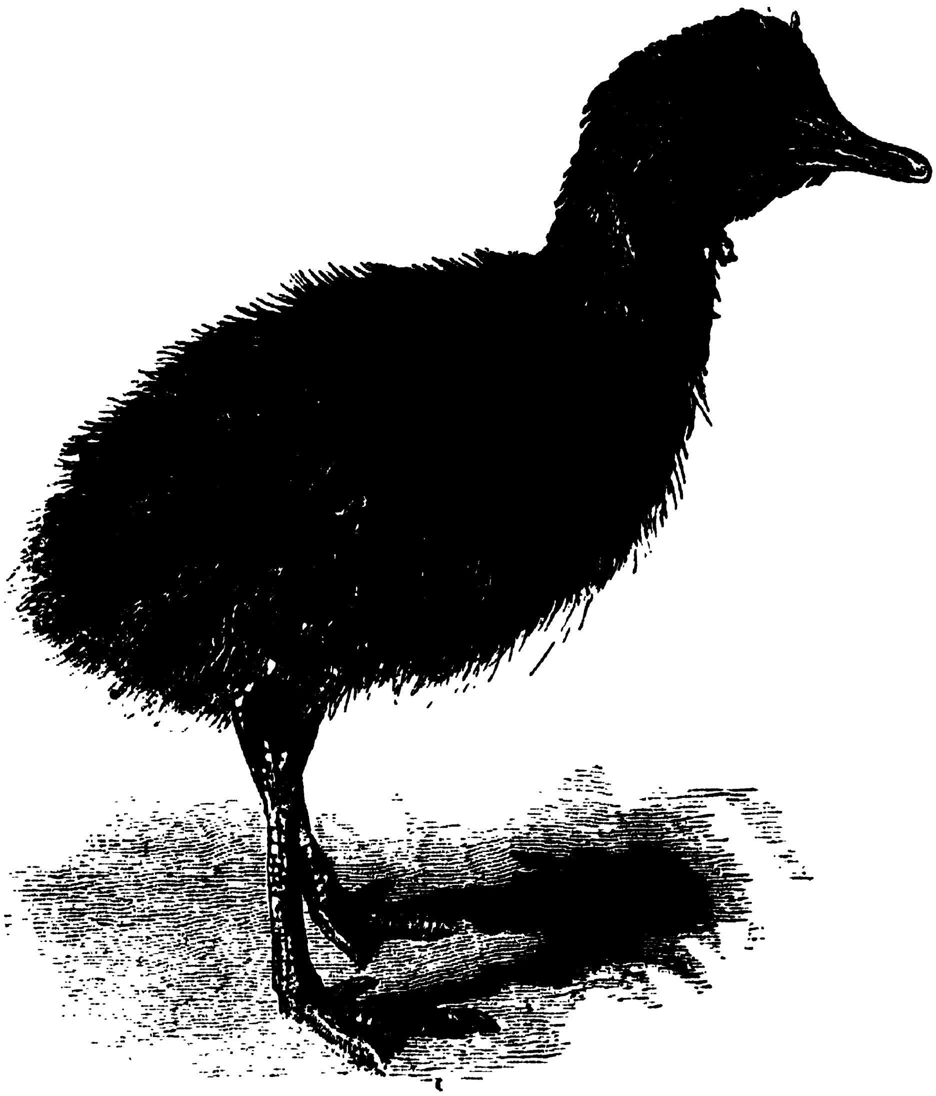

FIG. 5.—Young Cassowary.

a young cassowary, which the natives one day brought to him, with two eggs. He at once asked the natives to guide him to the nest, near which, in a bed of loose leaves, he placed the young bird, hoping to attract the old one. After the lapse of about ten minutes they suddenly heard the voice of the cassowary. This usually sounds like thunder, "but now, when calling its young, it reminded us of the lowing of a cow to its calf." Soon the beautiful blue and red neck of the bird became visible among the trees. The creature "stopped and scanned its surroundings carefully in the dense scrub, but a charge of No. 3 shot, fired from a distance of fifteen paces, laid it low." Six natives carried home the prize, which proved to be an unusually fine specimen of a male.

We cordially recommend this book to all who take an interest in anthropology and zoology, or in incidents of travel through unfamilar scenes. They will find in it much that cannot fail to give them genuine pleasure.

BRITISH EARTHQUAKES.

IT is somewhat remarkable that the ordinary notion that Great Britain has a special immunity from serious earthquake phenomena, still very generally obtains credit. An explanation of this popular fallacy may perhaps be found in the simple fact that, on the average, few people living at any one time chance to have experienced any considerable shock; whilst in the case of those few—we except the many who were affected by the disastrous Essex earthquake five years ago—who have felt the sensation, as a momentary mental impression it has been soon forgotten. It should, however, by this time be more generally known and accepted that no part of the habitable globe is entirely exempt from seismic action, and that earth-tremors of considerable amplitude and intensity are by no means necessarily connected with volcanic disturbances, as was formerly supposed. When it is duly recognized that, at the lowest computation, 600 disconnected shocks are known to have taken place in this country during the present era, the popular belief respecting "our tight little island" may well be entirely shaken. This number includes many earthquakes of considerable magnitude, and the additional seismological

evidence of modern compilations furnishes the testimony that as many as six or eight minor shocks have occurred annually in recent years. In evidence of the prevalence of such phenomena in England, it should be also remembered that it was on this island that Prof. George Darwin first discovered the fact of the continuous microseismic vibration of the earth's crust.

The new edition of the late Mr. William Roper's excellent summary of the principal earthquakes that have been recorded in Great Britain and Ireland during this era, which has lately been issued,[1] bears witness both to the frequency of such phenomena, and, even more strikingly, to the great advance that has taken place within recent years in the study of seismology in Britain. The increased attention which has been devoted to the subject is doubtless partly due to the extensive shock which occurred in this country in 1884.

The famous Catalogue compiled by Robert Mallet will ever remain the cyclopædic work of reference upon which all subsequent earthquake catalogues will necessarily be based; and the name of Mallet, as the authority, naturally figures most extensively in Mr. Roper's list. Until recently, it may, indeed, be said that the work of Mallet, and of M. Alexis Perrey, of Dijon, stood almost alone as the historical register of seismic force in the world. Within the last few years, however, the valuable experimental work of Prof. Milne and others in Japan, and of numerous European and American seismologists, has been supplemented by several treatises devoted to British earthquakes alone. Some of these publications—as the detailed report of the great Essex earthquake, and Mr. E. Parfitt's Devonshire Catalogue—being issued in connection with particular areas, and by local scientific bodies, have had a restricted application; whilst others, as Prof. O'Reilly's catalogue, and the one just mentioned, have included the entire British Islands in their scope. It was the intention of the present writer, when engaged, in conjunction with Prof. Meldola, upon the Report of the East Anglian earthquake,[2] to furnish a full list of British earthquakes; but, from the quantity of material accumulated from very many sources, it was found that so extensive a catalogue grew entirely out of proportion to the purpose of a special monograph, and only those disturbances which had similarly caused structural damage were included in that memoir. These alone, however, number as many as sixty well-authenticated records, although Mr. Roper, in his catalogue, which, unfortunately, is very scanty in point of detail, omits fully 25 per cent. of these injurious shocks. But since his catalogue too modestly professes to include only "the more remarkable earthquakes," it is to be expected that numerous omissions might be noticed, and we could readily add to his list over two or three dozen records (both mediæval and modern) which fully equalled the average intensity of those he has included. In fact, while it may be said to form the most comprehensive list of British earthquakes that has yet been produced, it is incomplete, and it is much to be regretted that the compiler did not survive to finish his erudite undertaking, as is explained in a prefatory note by his son.

Mr. Roper has, in effect, unconsciously erred unduly on the side of moderation, since he includes most of the fabulous stories that belong to mediæval times, while he has omitted many important shocks. This recalls a somewhat strange incident in connection with the 1884 earthquake—namely, that more damage actually occurred in the out-of-the-way villages chiefly affected by the shock than was ever reported in the London newspapers—a fact which does credit to the caution exercised by the daily press writers at the time. Too much, on the other hand, was made of the really slight but widely distributed shock which took place on May 30 in the present year, when no displacement of furniture nor stoppage of clocks then resulted; the experience being limited to the rattling of windows and the swaying of walls, as may be seen on referring to the summary which appeared in NATURE for June 6 (pp. 140–42).

Covering so considerable a period of history, and including so much subject-matter, Mr. Roper's work certainly deserved a more extended treatment than it has received. An introductory analytical chapter would have added considerably to the interest of such a catalogue, while a fuller elaboration and thorough editing would have advantageously extended the work beyond its unpretentious limit of fifty pages. The convenient method adopted by Mr. Roper of inserting a preliminary list of "principal authorities cited," is almost compulsory in such a work, for the purpose of establishing a code of abbreviations for subsequent use in the columns of the list; but the titles are generally given imperfectly or incorrectly, without the requisite details of publication, while the dates, where given, are not throughout those of the original, as they should be, but of later reprints. These and similar slight defects are inconvenient in an historical treatise, and we hope they may receive attention in the event of another edition of this interesting list being called for.

The total number of distinct earthquakes included in this catalogue—regarding the series of repeated shocks which sometimes take place within a brief period as a single record—amounts to 582, and an analysis of these records may be of interest here, as furnishing some slight indication of the chronological distribution of the chief seismic disturbances which have been accounted in British annals as having taken place within our area. They may, for convenience, be arranged as they occurred during each century, and term of 500 years: thus—

1st century	6	
2nd ,,	5	
3rd ,,	8	Total during the 1st 500 years 34
4th ,,	9	
5th ,,	6	
6th ,,	7	
7th ,,	6	
8th ,,	7	,, ,, 2nd ,, 28
9th ,,	3	
10th ,,	5	
11th ,,	27	
12th ,,	28	
13th ,,	26	,, ,, 3rd ,, 97
14th ,,	12	
15th ,,	4	
16th ,,	20	
17th ,,	36	
18th ,,	132	,, ,, 4th ,, 423
19th ,, (to 1889)	235	

It may perhaps be fairly assumed from this table that no true estimate of the actual number of shocks happening within each period can be arrived at, for the chief reason that the records are entirely subject to the irregularities of the few capable observers of the early centuries. It is to be observed that 423 shocks, or nearly 75 per cent. of the total number, have occurred since 1600, which may be considered as the period from which the more trustworthy accounts commenced. There is no reason whatever for supposing that the frequency of seismic shocks has increased since that period; and the evidence indicates little more than the activity of the observers, who appear to have fallen off considerably at times, as during the fourteenth and fifteenth centuries. This point is worth remarking, on account of the misleading statement that has been more than once made,

[1] "A List of the more Remarkable Earthquakes in Great Britain and Ireland during the Christian Era." Compiled by William Roper, F.S.S., F.R.Met.Soc. (Lancaster: Thos. Bell.)

[2] "Report on the East Anglian Earthquake of April 22, 1884." By Raphael Meldola, F.R.S., &c., and William White. (Essex Field Club Special Memoirs, vol. i.) (London: Macmillan and Co., 1885.)

that the twelfth century was specially subject to earthquakes.

Since the development of telegraphy, and the consequent rapid production of daily press news, the means of recording such phenomena with prompt accuracy has of course been greatly facilitated. This is very apparent when the number of shocks which have occurred within the present century is apportioned into decades of ten years. Thus—

In 1800–10	there were	9	shocks recorded.
,, 1811–20	,,	36	,,
,, 1821–30	,,	23	,,
,, 1831–40	,,	49	,,
,, 1841–50	,,	27	,,
,, 1851–60	,,	12	,,
,, 1861–70	,,	25	,,
,, 1871–80	,,	18	,,
,, 1881–88	,,	34	,,

Making a total number, between 1800–88, of 233 shocks.

Although it appears from this artificially divided list as if a low decade was followed, as a rule, by a high decade, the number being often doubled, no safe computation whatever can be inferred; and the more one considers the facts accumulated, the more one feels that there is no real evidence upon which the various conjectures respecting earthquake periodicity have been made. About a dozen only of the numerous Comrie shocks are included in the above figures, but even this number is sufficient to materially affect any such calculation, whilst very many other well-authenticated shocks, as already mentioned, are omitted in Mr. Roper's list. With regard to Comrie, in Perthshire, it may further be remarked that, during the month of October 1839, as many as sixty-six separate shocks are reported to have taken place; and during the years 1839-42, altogether upwards of 200 vibrations were experienced in that district (*vide* NATURE, vol. xxiii. pp. 117 and 170).

With regard to the trustworthiness of the earlier records, it may be generally assumed that some earth vibration did actually take place at the time stated, notwithstanding the exaggerations and extraneous notions that were mixed up with such phenomena in superstitious times. But whether the occurrence was in every case an earthquake in the proper sense of the term is open to doubt. It is, indeed, highly probable that such occurrences as that recorded under the date of June 7, 1750, and other more recent cases, were not earthquakes at all, but the effect of bursting bolides, similar to the phenomenon which was described very fully in *Symons's Meteorological Magazine* for December 1887. Others, again, appear to have been no more than extensive landslips, or other superficial rock displacements resulting from aërial denudation; while some others were probably only connected with violent storms, or the frost-cannonadings which are commonly produced on exposed chalk cliffs during the winter season.

The absurd statements that were made respecting some of the older occurrences are evidently either intentional or unintentional falsehoods; but many of them contain so much quaint humour that a few samples are well worth quoting. In the year 132 A.D. there was a terrible earthquake in England, when "men and cattle were swallowed up"; but this fashion in recording events had been set at least twenty-nine years earlier, for in the year 103, "a city is said to have been swallowed up." In 418 there was one that was "great and general; then famine, plague, hail, snow, cold, and meteors." In 505 one lasted for three hours. At about three o'clock on August 11, 1089, there was a terrible one in England, which caused great scarcity of fruit, and a late harvest; while twelve years later there was another that "terrified all England with a horrid spectacle, for buildings were lifted up and then again settled as before." Again, in 1177, near Darlington, "the earth swelled up to a great height from nine in the morning to the setting of the sun, and then with a loud noise sank down again"; there was another that took up all the day in 1110; while on September 11, 1275, a great earthquake was felt in Newcastle, with "dreadful thunder and lightning, blazing stars, and a comet, ... with the appearance of a great dragon, which terrified the people between the first and third hour of the day." This savours somewhat of the Chinese dragon fables, while some others almost match the deluge of Noah in their vast extent. In 974, for instance, "a great one shook the whole of England"; while earlier still, in 856, one occurred "over the greatest part of the known world." In 1133, "in manie parts of England an earthquake was felt so that it was thought that the earth would have sunke under the feete of men, with such a sound as was horrible to heare." In 1290, there was one felt in England that was described as being "nearly universal (!) in Europe"; while we are assured, with circumstantial evidence, that, in the year 1426, "on the even of St. Michael the Archangel, in the morning before day, betwixt the hours of one and two of the clocke, beganne a terrible earthquake, with lightning and thunder, which continued the space of two houres, and was universal through the world. The unreasonable beasts rored and drewe to the townes with hideous noise; also the fowls of the ayre likewise cried out."

Space does not permit of other equally curious accounts, as marvellous almost as the more primitive traditions of patriarchal times regarding the vindictive forces of Nature.

Whatever may be said about the accompaniments and absurd effects which have been ascribed to earthquake action, the majority of those shocks which are recorded as having caused damage to buildings may fairly be set down as facts, and although they may have occasionally been exaggerated, some of the details are generally authentically described.

A curious problem may be raised with regard to the effect of earthquakes upon river courses. That shoals have frequently been produced along marine coasts is well known, a striking case being that which happened early in January 1885, off Malta, to the extent of dangerously affecting navigation; but there are several accounts which agree in the assertion that the beds of such navigable streams as the Trent and the Thames have been temporarily raised by local earthquakes so as to permit of people "passing over dry-shod." What became of the river course during the operation is a problem that does not appear to have required solution. Yet sufficient circumstantial evidence has been produced, in connection with the shock in 1110 at Nottingham, and in 1158 at London, to almost warrant the idea that a certain amount of credence may be given to the stories. Whether it may be inferred from such statements that a change in the bed of the rivers in question then took place is doubtful, as history yields us no information on the point.

As a general statement we may safely infer finally that earthquakes in Great Britain, including the microseismic disturbances which are now so frequently recorded, were as common in the past as in the present period of more scientific observation; though, fortunately, such calamitous results as attended the catastrophe in Essex within recent times continue to be rare. It is still a matter for regret, however, that no steps have yet been taken to establish seismographs in different parts of this country. Until this is done, the chance records of various individuals—whose impressions, being inevitably affected more or less by the personal equation, produce only doubtful data—must continue to take the place of precise observation

WILLIAM WHITE.

EFFECT OF OIL ON DISTURBED WATER.

GENERALLY speaking, proverbs are the resultant expression of observed facts, but the efficacy of oil upon troubled waters would appear to be a proverb which, instead of being preceded by and founded upon trial and experiment, has rather led to the scientific demonstration and establishment of the truth it asserts. From the very earliest ages the effect of oil when poured upon disturbed water appears to have been widely known. Aristotle mentions it, and accounts for the phenomenon by assuming that the thin film of oleaginous matter into which oil resolves itself when poured upon water prevents the wind from obtaining a hold upon the water, and so checks the wave formations which are the usual results of wind at sea. Pliny, too, observes that among the officers of his fleet the soothing influence of oil was matter of common knowledge, and that the Assyrian divers were in the habit of sprinkling the surface water with oil when they wished to smooth down ripples, and so obtain a better light for prosecuting their work below. Coming down to more recent times, the custom of oiling the waves with a view to facilitate navigation would appear to have fallen into desuetude. Benjamin Franklin, however, seems to have been led, from observing the effect of pouring overboard some greasy water, to test its potency in a thoroughly scientific manner, when on a voyage across the Atlantic. Having experimented with great success upon the surface of a pond near London, he tested the effects of oil upon the sea itself. A stormy day was chosen, and from a boat, some half a mile from the beach at Portsmouth, oil was poured upon the sea. The experiment met with a very small share of success, for, while a greasy patch of water was discernible right to the shore, the surf continued to break upon the beach with unabated vigour. Subsequent and recent investigation has confirmed Franklin's finding, and proved that the greatest benefit derived from the use of oil is obtainable in deep water, where wave-motion is merely undulatory. When a shore-approaching wave ceases to find enough depth to impart to its neighbour its peculiar undulatory motion, it is no longer a wave pure and simple, but becomes an actual moving body of water which moves rapidly forward, until it breaks with great violence upon the shore; upon such waves as these, oil has little or no effect.

The knowledge of the influence of oil upon a rough sea has long been known to those engaged in the whale and seal fisheries, and its application is of common occurrence. When their vessels or boats are overtaken by a storm, they usually, by means of a drogue or sea anchor, make what is nautically termed a dead drift, *i.e.* they suffer themselves to be slowly drifted before the wind. In such circumstances as these, the application of oil to the waves insures that the area into which the boat drifts is one of calm, as the oil spreads more rapidly than the boat moves, and consequently prepares a smooth patch for the vessel to drift into. If the captain, however, prefers to run his vessel before the wind, then she ranges ahead of the oiled patch, and thus the effect of oiling the waves is very materially discounted.

The native Eskimo, when engaged in transporting his family from place to place, always insures a smooth passage for the *oomiak*, or women's boat, by trailing a punctured skin filled with oil from the stern of his *kayak*, which he propels at some considerable distance ahead of the boat containing his wife and children.

Within the last twenty years many well-authenticated instances have been placed on record as to the potency of oil as a water-soother, but unfortunately the value of such reports is very much diminished by the ship-masters neglecting to explain the relative position of their vessel in regard to the wind and sea. The British warship *Swiftsure*, when on a voyage from Honolulu to Esquimault, encountered a gale accompanied by tremendous seas. A bag, punctured with the point of a knife, was filled with oil and rigged out on the weather side of the vessel. This had such a marked effect, that the vessel rode bravely through the gale, and reached her destination in perfect safety. On October 8, 1880, a Mr. Fondacaro left Monte Video for Naples in a three-ton boat. He arrived at Malaga on February 4, 1881. On his voyage across the Atlantic, he had repeatedly to lay-to during stress of weather, and reports that he considered his safe arrival entirely due to his use of oil. A gallon of olive-oil would last him, when hove-to, for twenty-four hours. He gives it as his experience that oil does not diminish the size of the waves, but renders them comparatively harmless by preventing their breaking. There is a consensus of opinion among those who have tested the use of oil, that a small quantity is quite as efficacious as a larger one, a consumption of one pint per hour being sufficient. Small as this quantity is, the extreme expansibility of oil when floating upon the water renders it quite adequate. Thus a ship running 10 knots an hour will leave behind her a wake some 10 knots by 40 feet, covered with a thin film of oil.

The Dunkirk Chamber of Commerce, fully alive to the vast importance of the use of oil as materially conducing to safe navigation, have just reported on the results of some tests made at their direction among the French fishing fleet off Iceland. One master reports that by its use he was enabled to ride out successfully a prolonged and severe spell of bad weather, which compelled his *confrères* to run to port until the weather moderated. The Chamber rewarded him with 100 francs. Other captains who have reported in detail the result of their experiments, agree with him in stating that, for small vessels experiencing stress of weather in deep water, the use of oil cannot be too highly recommended.

Nor is the utility of oil confined alone to this branch of marine navigation. Advices just received from New York furnish some interesting particulars relative to the towage of the disabled steamship *Italia* of the Hamburg American Company. The *Italia* broke her shaft whilst proceeding from Havre to New York. In this condition she was taken in tow by the *Gellert*, of the same company. The towing hawsers—6-inch steel wire—were lengthened by heavy chain cables until the distance between the two vessels was increased to 1000 feet. Unfortunately, a heavy gale from the north-west caused a dangerous sea to arise, and it was feared that the *Italia* would have to be abandoned. As a last resort, a can of oil with a small hole in the bottom was set over the stern of the *Gellert*. The effect, according to the master, Captain Kampf, was magical. The seas broke over the bows of the *Italia* with much less fury, merely surging past in a heavy swell, while the tension on the cable was immediately relieved, and the *Gellert* was enabled, in spite of continued bad weather, to reach New York in safety, having towed her charge continuously for the distance of 750 miles. Possibly many cases of abandoned towages in bad weather might be averted did the masters of tugs but try the effect of a little oil prior to casting the vessel adrift.

The true part played by this oleaginous film in diminishing the disturbance of the sea seems to be that of a lubricant. Waves are formed by the friction of wind and water. Any force, therefore, that tends to lessen the friction reduces the violence of the waves. As far as is at present known, animal or the heavier vegetable oils form the best lubricant between the two elements. Mineral or fossil oils, which possess less viscosity and are less oleaginous in their mechanical properties, exert much less influence upon the water. This anti-frictional force of oil can hardly be over-estimated. The Atlantic waves have been calculated to exert an average pressure

during the winter months of 2086 pounds per square foot. During a heavy gale this pressure is increased to 6983 pounds; yet the thin oil blanket is sufficient, when applied under certain conditions, to enable a vessel to navigate through them in perfect safety, their oiled summits raising themselves in sullen grandeur, but never breaking aboard. What the exact coefficient of friction between air in motion and water is, and the proportion of its reduction by oil or other lubricants, are questions that open up a most interesting subject of inquiry, the resolution of which will prove highly beneficial to the whole nautical and mercantile world.

Numerous experiments have been made with a view to testing the utility of oil in smoothing the approaches to exposed harbours in rough weather. The tests undertaken at Peterhead have met with unqualified success. The *modus operandi* has been to lay leaden pipes along the bottom of the harbour, taking care to keep the pipes stationary by means of concrete. The pipe is provided with numerous roses for disseminating the oil. When rough weather comes on, oil is forced along the pipes, and it escapes into the water through the apertures provided, and then, its specific gravity being less than that of water, it rises to the surface and quickly renders the sea less turbulent and the passage into the harbour quite safe. Another method employed to render safe ingress into harbours in bad weather is that of firing out to sea an oil-carrying projectile. This consists of a heavy tin tube weighted with lead at one end. The tube is filled with two or three quarts of oil, and the aperture stopped. When the projectile is fired from a gun or mortar, it reverses, and, the time-fuse exploding, the powder blows out the plug, and the liberated oil falls into the sea. A series of experiments, conducted by a Committee appointed by the United States Life-saving Service to inquire into the practical utility of oil-carrying projectiles, goes to confirm the statement made above, viz. that the power of oil to subdue the force of the waves in shoal water, or to prevent the waves breaking in surf, is very small indeed. There is one point, however, upon which all authorities who have tested the use of oil at sea are agreed. As an adjunct to the equipment of ships' boats it is simply invaluable. Many a shipwrecked crew have been enabled to keep their frail craft afloat until land was reached or a rescue effected, solely by its use. Nothing is more common among the records of shipwrecks than to read of the small boats either being swamped while at the vessel's side, or capsizing through stress of weather. In January 1884 the *Cambria* emigrant ship was run into by the *Sultan* in the North Sea, and, out of 522 on board, 416 were drowned. Of the four starboard boats, no less than three capsized, and all their occupants perished. In the collision in the Channel between the *Forest* and *Avalanche*, two out of three boats which left the *Forest* were swamped, and all on board lost their lives. These are but two instances out of many where lives *might* have been saved by the use of a little oil.

The subject of saving endangered life at sea is one that always enlists the deepest sympathies of all sorts and conditions of men. The perusal of the "Annual Wreck Chart," published by the Board of Trade, or of the lamentable records of personal sorrows and destitution consequent upon the disasters around our coasts, suggests the possibility that the loss of life might be considerably reduced by a practical knowledge of the best methods of applying oil during storms at sea. We think that much might be done by its use to facilitate the launching of boats from distressed vessels, and their safe subsequent navigation. Harbours of refuge on exposed coasts might be established at a very small cost.

In one department alone of our maritime industry, deep-sea fishing, many lives might be saved. At present, the mortality among the carriers, *i.e.* those engaged in carrying in small boats the fish from the smacks to the steam despatch-boats, is very great. Their boats might be equipped, at a very low cost, with oil-tanks or oil-bags to be used when trans-shipments are being effected in heavy weather. Already the Governments of the United States and Germany have realized the vast importance of this subject, and have instituted an exhaustive series of experiments with the view of rendering compulsory the carrying of oil for use as a life-saving equipment. When that complex and overburdened instrument of government, the Board of Trade, was asked in Parliament to cause experiments to be made relative to the use of oil at sea, the reply was, that there were no funds available for the purpose; that the Board could not spend money or become investors in such schemes. The Consultative Committee appointed under the Life-saving Appliances Act of last year have, however, suggested oil-bags, among other equipments, to be carried by boats and rafts. At the International Maritime Conference at Washington, U.S., this subject has received the attention its importance merits. Further, the National Life-boat Institution and the National Sea Fisheries Protection Association have amalgamated their forces with a view to testing the efficacy of oil, but as yet the results of their investigations have not been published. While it is very gratifying to know that the man of science and the philanthropist are ready to explore the practical utility of this question, we cannot hope for any satisfying material results until the Board of Trade sees its way to take administrative action in the matter, and to deal in a fitting manner with a question that is so indissolubly connected with the interests of all classes of this great mercantile community.

RICHARD BEYNON.

RECENT OBSERVATIONS OF JUPITER.

OBSERVATIONS of Jupiter have been conducted under great difficulties during the past opposition in consequence of the low altitude of the planet. His elevation, even at meridian passage, has only been about 16°, as observed in this country, so that the study of his surface markings has been much interrupted by the bad definition which usually affects objects not far removed from the haze and vapours on the horizon. It is, however, important that planetary features, especially those which exhibit changes of form and motion, should be watched as persistently as circumstances allow, and with this purpose in view Jupiter has been submitted to telescopic scrutiny whenever the atmosphere offered facilities for such work during the past summer and autumn. Few opportunities occurred, however, during the latter season owing to the great prevalence of clouds, and on the several nights sufficiently clear for the purpose, the atmosphere was unsteady and the definition indifferent; thus the more delicate lineaments of the planet's surface could be rarely observed with satisfactory distinctness.

The great red spot was visible on the night of May 21, 1889, and it was estimated to be on the central meridian at 12h. 31m. Further views of the same object were secured in June, July, and later months. In appearance and form it presented much the same aspect as in preceding years. Its elliptical outline is still preserved, and there seems to have occurred no perceptible change in its size. It is somewhat faint relatively to the very conspicuous belts north of it, and it is only on a good night that it can be well recognized as a complete ellipse with a dusky interior. On the evening of September 12 last, I obtained an excellent view of it with my 10-inch reflector, power 252. The spot was central at 6h. 33m., and its following end was seen to be much the darkest. This has usually been the case, and I have often noticed a very small, black spot at this extremity. Another observation was effected on the early evening of November 26, when the spot crossed the planet's centre at 3h. 54m., but the

exact time was a little uncertain, the conditions being far from favourable. Possibly the spot may have effected its passage a little before this time, as from several views of the following end of this object at about 4h. 30m., I concluded my estimate might be a trifle late, but in any case the error would be small.

Comparing the observation on November 26 with that recorded on May 21, it will be found that in the interval of 188·64 days the red spot completed 456 rotations, and that its mean period was 9h. 55m. 40·15s. This is nearly identical with the rotation period I found for the same object in 1888, when it was 9h. 55m. 40·24s. (462 rotations), and in 1887, when the figures were 9h. 55m. 40·5s. It is evident from these several determinations that during the last three oppositions the motion of the spot has been very consistent and equable. There has been a slight acceleration perhaps in velocity, inducing the rotation period to become a little shorter, but the differences are so small that they may well be covered by the observational errors which cannot be altogether eliminated from work of this character, and particularly at a time when the object observed is unfavourably placed. In any case the red spot has rotated with more celerity during the last year or two than in 1886, when its mean period was 9h. 55m. 41·1s., to which it had gradually increased from 9h. 55m. 34·2s. in 1879–80. These variations of motion may be regularly effected in a cycle, and it will be very important if future observations can determine the exact period.

The white spots near the equator of Jupiter are still occasionally visible, but it has not been feasible to secure views of them of a sufficiently exact nature to deduce their rotations. In recent years the apparent velocity of these objects has been decreasing, for while in the autumn of 1880 their period was 9h. 50m. 6s., it was found, from many observations of similar markings by Mr. A. Stanley Williams, of Brighton, in 1887, that it had increased to 9h. 50m. 22·4s.

Since 1884 a number of white spots have been also observed on the northern borders of the great northern equatorial belt. The period of these is but very slightly less than that of the red spot. On September 12, I observed one of these situated in a longitude not far preceding the west end of the red spot, and it appeared to have divided the equatorial belt with a vein of bright material. There was another object of the same kind following the red spot, but in this case the continuity of the belt was not interrupted, the bright matter appearing as a slight indentation in its northern side. These markings are shown in a drawing of Jupiter made by Mr. Keder with the great Lick refractor, power 315, on September 5 last, but they are not delineated in quite the same characters as seen here. The drawing alluded to is perhaps the best and the most replete with detail of any I have ever seen of this planet, and it furnishes clear testimony that the defining properties of the 36-inch telescope are of the highest order.

The curiously curved belt immediately north of the red spot is still one of the most prominent features on the planet's disk. It forms the southern half of the great south equatorial belt which is double. Under the ends of the red spot it suddenly dips to the north and runs into the other half of the belt. In recent years the curved belt has been very dark and pronounced in the region contiguous to the following end of the red spot, and upon its crest there have been condensations of extremely dark matter. Under the preceding end of the spot this belt is, however, more delicate in tone, and it looks like a mere pencil shading.

During the few ensuing years these interesting features may be studied to greater effect, as the planet will assume a more northerly position, and rise above the vaporous undulations which have recently much interfered with observations of his surface.

W. F. DENNING.

NOTES.

DR. ARCHIBALD GEIKIE, F.R.S., has just received a diploma of membership of the Kaiserlich Leopoldinisch-Carolinisch Deutsche Akademie der Naturforscher, the oldest scientific Society of Germany.

SIR JOHN LUBBOCK'S name appears in the list of those who have received New Year's honours and appointments. He has been made a member of the Privy Council. A baronetcy has been conferred on William Scovell Savory, F.R.S., President of the Royal College of Surgeons.

THE Paris municipality proposes to do honour to the memory of Darwin by naming a new street after him.

A COMMITTEE has been formed in Paris for the purpose of preparing the way for the erection of a statue of the late M. Boussingault. His scientific researches were of so much service to industry, especially to agriculture, that the Committee ought to have little difficulty in obtaining the necessary funds.

THE death of Sir Henry Yule, which we regret to have to record, is a great loss to geographical science. He died on Monday, in his seventieth year. His masterpiece was his splendid edition of the "Book of Ser Marco Polo"—a work to the permanent value of which he added largely by his learned and luminous notes.

WE regret to announce the death, after an illness which lasted some months, of M. Eugène Deslongchamps, of the Château Mathieu, Calvados. He was formerly Professor of Zoology and Palæontology at the Faculty of Sciences at Caen, and a member of the committee of the "Palæontologie Française." He was the son of the celebrated French palæontologist, Prof. Eudes-Deslongchamps, and published several memoirs on the palæontological fauna of Normandy, ranging from Brachiopoda to the Crocodilia. His best known memoirs are the "Prodrome des Teléosauriens du Cavaldos" and "Les Brachiopodes des Terrains Jurassiques."

GERMAN papers announce the death of Dr. Karl Edward Venus, an eminent entomologist, and founder of the Entomological Society "Iris," at Dresden. He died on December 13.

THE Congress of Russian men of science and physicians is now holding its eighth meeting. Work began on December 28, and will go on until January 7.

THE general meeting of the Association for the Improvement of Geometrical Teaching will be held in the Botanical Theatre, University College, London, on Friday, January 17. At the morning sitting (11 a.m.) the reports of the Council and the Committees will be read, the new officers will be elected, and various candidates will be proposed for election as members of the Association. After an adjournment for luncheon at 1 p.m., members will reassemble for the afternoon sitting (2 p.m.), at which papers will be read by the Rev. Dr. C. Taylor, on "A New Treatment of the Hyperbola"; by Mr. G. Heppel, on "The Teaching of Trigonometry;" by Mr. E. M. Langley, on "Some Geometrical Theorems"; and by the President (Prof. Minchin), on "Statics and Geometry."

THE Annual Conference of the Principals of the University Colleges was held on Tuesday at the Durham College of Science, Newcastle-upon-Tyne, Principal Garnett occupying the chair. The Principals were subsequently entertained at dinner by the chairman. Several questions affecting the interests of the Colleges collectively were discussed at the meeting, and it was decided on the invitation of Principal Reichel that the next gathering should be held at University College, Bangor.

THE Paris Municipal Council has lately instituted two new scientific chairs in the Hotel de Ville. One of them is devoted

to the study of the history of religions. The other is a Chair of Biology, and has been entrusted to Prof. Pouchet, of the Natural History Museum, who delivers a course of general lectures on the fundamental ideas relating to zoology, anatomy, life, &c.

AT a meeting of the Senate of the University of Sydney, on November 4, 1889, a letter from Dr. Haswell was read, intimating his acceptance of the Senate's offer of the Challis Professorship of Biology, to take effect from March 1, 1890.

AT the annual meeting of the Manx Geological Society on December 28, in the Peel Grammar School, Dr. Haviland, the retiring President, referred with pleasure to the fact that early in the summer Mr. Robert Russell had been sent to prosecute the geological survey of the Isle of Man. Dr. Haviland was also able to congratulate Peel on the prospect of a system of technical education being established in Christian's School, under the auspices of the Cloth Workers' Company and Sir Owen Roberts.

MR. A. V. GARRATT, Secretary of the American National Electric Light Association, has sent to the members a circular letter, asking them to state briefly the hardest electrical problems they meet in their investigations or in the conduct of their electrical business. He asks them also to state what feature of their business is the least economical or efficient, and why, and where the greatest economy could be effected if the difficulty could be overcome. The answers to these queries will be digested, and the results submitted to Prof. Henry A. Rowland, of Johns Hopkins University. Prof. Rowland has consented to address the next Electric Light Convention at Kansas City in February, basing his remarks upon the problems suggested by the members, and pointing out the direction in which their solution must be sought.

M. VICTOR GIRAUD, the African explorer, has just published the narrative of his explorations in the African Lake Region from 1883 to 1889. The work contains many illustrations.

THE fourth volume of M. Grandeau's "Études Agronomiques," just issued, contains a review of British and American agriculture, as represented at the Paris Exhibition.

AN historical sketch of the geographical works relating to Russia has been compiled by Baron Kaulbars under the auspices of the Imperial Geographical Society of Russia, in which the author endeavours to show the respective parts played by the army and navy, with various scientific societies, in the exploration and representation of the Empire. Beginning with the map found by Dr. Michof in St. Mark's library, Venice, only five years ago, and dating back to 1525, he traces all the labours, geographic and geodetic, referring to Russia. The astronomer Struve figures well among the latter workers in the measurements of various meridian arcs and the determination of differences of longitude, whilst few can speak with more authority than Colonel Baron Kaulbars himself on the geographical portion. Hydrographical labours began with Peter the Great, and all similar undertakings completed by the Russian navy have been brought together; the bibliographical sketch commencing with the Baltic Sea, as being the most important in the history of the navy. In the chapter chronicling the works of scientific societies, accounts are given of the many explorations into Siberia and Arctic regions. A long and complete list of all maps due to Russian topographers is also given in historical sequence, together with the various scales used.

THE Report of the Kew Committee for the year ending October 31 last contains an interesting account of the experiments carried on at the Kew Observatory; the list of instruments verified, especially clinical thermometers, Navy telescopes and sextants, and of chronometers and watches rated, is a sufficient test of the value set upon the certificates given. The death of Mr. De la Rue, the Chairman of the Committee, will be much felt, as he was one of the most munificent benefactors of the Observatory, and it was at his suggestion that the first photoheliograph was constructed and brought into use there. The complete sets of magnetic, meteorological, and electrical instruments have been kept in perfect working order, and summaries of the results for the year's working are given in the appendices to the Report. Sketches of sun-spots have been made on 173 days, and the collection of solar negatives taken between 1858 and 1872 have been handed over to the Solar Physics Committee, with a view to their utilization. A good whirling machine has been erected, for the purpose of examining the accuracy of small anemometers and of the air-meters employed in measuring air-currents in mine-shafts, &c. In accordance with a resolution of the International Meteorological Committee, a thermometer of very low range has been constructed, to be used as a standard spirit thermometer for temperatures ranging from zero to about $-70°$ C.

MESSRS. SAMPSON LOW have issued, with Mr. Stanley's permission, a shilling volume, containing "The Story of Emin's Rescue as told in Stanley's Letters." It has been edited by Mr. Keltie, who contributes an introduction bringing the narrative of the Emin Pasha Relief Expedition up to the date at which the first of Mr. Stanley's letters was received. A map, showing Mr. Stanley's routes and discoveries, is included in the volume.

AT the meeting of the Photographic Society on December 10, Mr. G. M. Whipple read an interesting and valuable paper on photography in relation to meteorology. There are now 32 observatories—8 in this country, 7 in the colonies, and 17 abroad—in which photographic apparatus is used for meteorological observations.

AT the meeting of the French Meteorological Society of December 3, 1889, M. Wada gave an account of the cyclone which ravaged the southern and eastern part of Japan on September 11 and 12 last. The centre of the storm followed a course towards N. 35° E., progressing at a rate of 30 to 43 miles an hour, the velocity of the wind reaching 65 miles an hour. The barometer fell to 28·23 inches—a reading which is only known to have occurred once before in Japan. This storm raised an enormous wave, said to have been nearly 20 feet above high-water mark, and which carried away 3000 houses. M. Ritter explained his experiments upon the artificial production of clouds in liquids and gases. With regard to the clouds in the atmosphere, the author distinguishes two principal kinds—viz. (1) the "stratus" and semi-transparent mist, and (2) the ordinary forms, such as "cumulus," &c., and he deals with them from two points of view: the diffusion of vapour according to Dalton's law, and the transference of clouds by the movement of the air. He referred to the different results produced from these conditions, with regard to suspension in the atmosphere, &c. The details of the paper will be published in the *Annuaire* of the Society.

THE *Jaarboek* of the Royal Meteorological Institute of the Netherlands for 1888 is the fortieth of the series, and contains, in addition to the daily observations and summaries at various stations a summary of phenological observations for 1879–88, and observations at Parimaribo, Jeddah, and from the Upper Congo. The preface contains an explanation of the conventional signs used in this long series, and of the curious errors which have occurred from time to time; a reference to this volume is therefore necessary to anyone who wishes to make use of the

observations of previous years, as the errors are not all typographical; for instance, the wind is given during a year and eight months in kilometres per hour instead of ¼ kilometres. But, notwithstanding certain defects and peculiarities of methods, the Institute has been consistent in keeping to one and the same plan, from a period at which the publication of systematic observations was in its infancy.

THE trustees of the Missouri Botanical Garden, in accordance with the intention of its founder, have set a good example by establishing six scholarships for garden pupils, the object being to provide theoretical and practical instruction for young men desirous of becoming gardeners. The course of instruction will extend over six years, and will include thorough training in every department of work in which practical gardeners are interested.

FROM the latest Report of the School of Mines and Industries at Bendigo, Victoria, we are glad to learn that this institution continues to make steady progress. In 1883-84 it had 324 students. The number in 1888-89 was 799. This shows, as the Council fairly claim, that the efforts of the school to supply scientific and technical education to miners, engineers, assayers, architects, pharmacists, artisans, art students, and others are thoroughly appreciated in Australia. Some of the students hail from Queensland, South Australia, and other distant parts.

THE fifth part of the second volume of the *Internationales Archiv für Ethnographie* has been issued. It maintains in all respects the high level reached by previous numbers. Among the contributions are an article in German, by F. Grabowsky, on death, burial, and the funeral festival among the Dajaks; and one in English, by Prof. H. H. Giglioli, on a singular obsidian scraper used at present by some of the Galla tribes in southern Shoa.

AT a meeting of the Philosophical Institute of Canterbury, New Zealand, on October 3, Mr. H. O. Forbes, Director of the Canterbury Museum, Christchurch, described an extinct species of swan from osteological remains which he had discovered while excavating a cave recently exposed at Sumner, on the estuary of the Heathcote and Avon Rivers, a few miles distant from Christchurch. The cave had been entirely concealed by the falling in of the basaltic rock overhanging the entrance. This great heap of *débris* had been there since the arrival of the first settlers at Canterbury, and had been quarried from for twenty-five years for the making of roads, without any trace of a cave being exposed till about the beginning of September. When the cave was first entered, there were found on the surface a few Moa bones, and various Maori implements—a well-made paddle, an ornamental baler, numerous greenstone adzes, obsidian flake scrapers, shell-openers, and ornaments carefully polished. In some of the latter, small holes for suspending them round the neck were drilled in the most beautiful manner. It is difficult to conjecture how the Maoris had accomplished this when European workers in greenstone find it a laborious process even with, and impossible without, a diamond drill. Besides these greenstone objects, there was a great quantity of fishing paraphernalia—stone suckers, fish-hooks of all sizes made out of Moa and other bones—all carefully and elaborately fashioned. Some of the larger fish-hooks were carved out of bones which must have belonged to a Dinornis of great size. On the floor of the cave was also found a well-carved representation in wood of a dog, which seems to have formed the terminating ornament of a paddle-handle—evidence that the Maoris were well acquainted with this animal. The femur of the Maori rat and a portion of the skin covered with dense reddish fur in perfect preservation were also obtained. A quantity of human hair was scattered about, both on the floor and in the kitchen midden in front of the cave. This midden was composed chiefly of marine shells of many kinds, and of the remains of fires and feasts. One large lock of long hair—evidently a woman's—was discovered in the midden tied up with great care at both ends with plaited flax, and incased in a plaited flax pocket. Some very fine bone needles also were come upon, but little thicker than steel needles, with an eye exquisitely drilled. There were, besides Moa bones, those of many other species of birds, of dogs, of fish, of seals (both fur and hair), and sea elephants—all of which had been used for food, but no human bones. Of the ornithic remains, some apparently belong to species now extinct in New Zealand, and not yet described. The bones and egg-shells of the Moa show incontestably that the Maori and it were contemporaneous. The geological evidence would seem to indicate that this cave was of considerable antiquity, and was inhabited at intervals for a long period of time. Several fire-places occur interstratified with bands of silt, as if the cave had been inhabited and then flooded many times. Definite conclusions on the geological evidence have not yet been arrived at. The swan bones discovered consist of three complete coracoids, the proximal and distal portions of the humerus sufficient to complete the whole bone. They differ very little from those of the *Chenopis atrata* of Australia, except in their greater size. The new species has been named *Chenopis sumnerensis*. It is smaller, however, than a species of swan discovered—as a complete skeleton—many years ago in Otago, some 18 feet below the surface of the ground, when the foundation for a house was being dug in Dunedin. This Sumner cave has been closed since before the introduction of the *Chenopis atrata* into New Zealand. The extension, therefore, of the Cygnidæ to New Zealand is a very interesting fact in ornithology. A similar cave, but far distant from the present one, was excavated and examined by Sir Julius von Haast (Mr. Forbes's predecessor) many years ago. Of the bones found in it, the Moa remains were fully described by their discoverer, but none belonging to the smaller birds have as yet been described. These with the osteological collections disinterred from the Glenmark and Hamilton swamps, and from the Earnscleugh Cave, will form the subject of a future paper by Mr. Forbes before the Institute.

IN a previous paper before the Philosophical Institute of Canterbury, Mr. Forbes pointed out that the bone figured by Prof. Owen on plate ciii. of his "Extinct Birds of New Zealand" as the coracoid of the *Cnemiornis*, belongs with little doubt to *Aptornis*. The coracoid of *Cnemiornis*, of which there are numerous specimens in the Christchurch and Otago Museums, is of the typical anserine form, and closely resembles that of *Cereopsis*. The coraco-clavicular angle in Aptornis approached 130°.

THE following curious instance of inheritance of an acquired mental peculiarity is given by Pastor Handtmann, of Seedorf by Lenzen on the Elbe, in the *Korrespondenzblatt* of the German Anthropological Society. When acting as substitute for a few months in 1868, in the parish of Groben, in Brandenburg, he there met a farmer named Löwendorf, who, when he signed his name officially in connection with the school, always wrote his Christian name "Austug" instead of "August." Some years later, the writer was inspecting this school, and heard a little girl read "Leneb" for "Leben," "Naled" for "Nadel," and so on. On inquiry, he found her name was Löwendorf, and she was a daughter of this farmer. The father (then dead) had in talk with his neighbours occasioned much amusement by the peculiar habit, which appeared to be the result of a fall from the upper story of a barn, some time before the birth of this girl. She wrote, as well as spoke, in the peculiar way referred to.

PROF. LEUMANN is of opinion (*Phil. Studien*) that the influence of blood circulation and breathing, on mind-life, has been too little

considered. He notices the parallelism between pulse acceleration and passion, the rush of ideas in fever, and so on. The differences of pulse and breathing in different persons are no less significant, and should be regarded in all psychometric determinations. The author noticed in boys of a Strasburg gymnasium, that in scanning verse, the number of feet spoken in a minute rose with the pulse-frequency. Even in one person, experimented on from midday till evening, the dependence of normal reading of metrical compositions on pulse-frequency was proved; the rhythmic intervals in scanning corresponded to the pulse-intervals. Leumann supposes that to be the most general and normal song-metre, whose feet correspond to the pulsations, and its lines to respiration. And, in fact, the Indo-Germanic original metre consists of four times four trochees, an arrangement agreeing with that view; from it arose the Nibelungen strophe and the hexameter.

IN the Legislative Council of India recently, Mr. R. J. Crosthwaite in introducing the amended Land Revenue (Central Provinces) Bill, said that many objections had been raised, chiefly by the Malguzars' Association of Nagpore, to the powers given by the Bill to the Chief Commissioner to make rules for the management of forests. To show that such powers were necessary, Mr. Crosthwaite instanced two cases of the wanton destruction of forests which is so common in India. In 1885 the Deputy Commissioner of Nagpore reported that the malguzar of Munsar had given a contract for the cutting and removal of the wood in the forest land of his mahal. The villagers had rights in this forest-land, and those rights were interfered with by the cutting of the wood; but, in spite of the Chief Commissioner, the malguzar continued the cutting, and the hills were completely stripped of all timber and brushwood. In another case a zemindar had sold the right to collect resin from his forest. The resin is obtained by girdling the trees, and it was found that in about four square miles of particularly fine forest every sab tree was killed outright. That is, four square miles of forest were destroyed to produce about 1200 rupees. Sir Charles Elliott, speaking on the same occasion, said that if some such provision as that now proposed had existed in the past, the forest clearances round Simla and along the southern slopes of the Himalayas abutting the Punjab plain could never have taken place.

MESSRS. DULAU AND CO. have issued a catalogue of works on chemistry and physics.

IN some copies of NATURE, last week, the following sentence appeared in the first paragraph of the Duke of Argyll's letter on "Acquired Characters and Congenital Variation": "But it implies the denial of 'congenital' causes." It ought to have been: "But it implies no denial of 'congenital' causes."

THE additions to the Zoological Society's Gardens during the past two weeks include a Malbrouck Monkey (*Cercopithecus cynosurus* ♂) from South Africa, presented by Mr. William F. Hughes; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Mr. Lawson N. Peregrine; two Viscachas (*Lagostomus trichodactylus* ♂ ♀) from the Argentine Republic, presented by Mr. Thomas Taylor; two Crimson-winged Parrakeets (*Aprosmictus erythropterus* ♂ ♀) from Australia, presented by Mrs. G. Byng-Payne; a Bonnet Monkey (*Macacus sinicus* ♀) from India, presented by Mr. James Entwistle; a Malabar Parrakeet (*Palæornis columboides*) from Southern India, presented by Mr. J. E. Godfrey; three Common Bluebirds (*Sialia wilsoni*) from North America, presented by Commander W. M. Latham, R.N., F.Z.S.; a Black Wallaby (*Halmaturus walabatus* ♂) from New South Wales, two Black and White Geese (*Anseranas melanoleuca*) from Australia, a Ring-tailed Coati (*Nasua rufa*) from South America, deposited.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m., January 2 = 4h. 49m. 56s.

Remarks.

(1) Described as "very bright, very large, very gradually brighter in the middle; barely resolvable." The spectrum was observed at Harvard College in 1869. The continuous spectrum extended from about λ 450 to 607. Two bright lines appear to have been observed, less refrangible than those of other nebulæ, but no reliable measures were made, owing to errors in the micrometer (Harvard College Observations, vol. xiii. part i. p. 64). Further observations are required, as all departures from the ordinary spectrum of bright lines are especially interesting in connection with the question of the variation of spectrum with temperature. Comparisons with the carbon flutings seen in the flame of a spirit-lamp, and the brightest flutings of manganese and lead, conveniently obtained by burning the chlorides in the flame, are suggested.

(2) In this star of Group II. the bands are very weak, only 2, 3, 7, 8 being well seen. The star falls in species 3 of the subdivision of the group, the manganese fluting (band 4) being absent because it is masked by the fluting of carbon near λ 564, and 5 and 6 being absent because the temperature is low. The carbon flutings appear to be brightest in the earlier species, and it seems probable that band 9 is also present but has been overlooked. This band is the dark space lying between the bright fluting of carbon 468–474 and the end of the continuous spectrum. Comparisons with the spectrum of the spirit-lamp flame, with special reference to the presence of the carbon fluting 468–474 are suggested. Dunér's mean value for the end of the band in other stars is λ 476.

(3) This is classed by Gothard with stars of the solar type. The usual observations are suggested.

(4) Gothard describes the spectrum of this star as Group IV., but is somewhat doubtful about it. It is probably either a late star of Group III. or Group V., as in either case the hydrogen lines would be moderately thick.

(5) This is a good example of stars of Group VI., in which Dunér records the bands 2, 3, 4, 5, 6, 9, and 10. The last three are carbon absorption flutings, and the only point to be noted in connection with these is the intensity of band 6 (near λ 564), relatively to the other bands. The first four are secondary bands, possibly produced by vapours similar to those which produce the telluric bands in the solar spectrum. Other absorptions may also be looked for.

(6) This is another variable of which no spectrum has been recorded. The range of variation is from about 8·5 at maximum to $<$ 13 at minimum, and the period is 294 days. The maximum occurs on January 2.

(7) This is a variable star of Group II., of the same type as those in which Espin has found bright lines of hydrogen at maximum. The number and character of the bands and the presence or absence of bright lines should be noted. The intensity of the bright carbon flutings and their fading away, if any, as the maximum (January 7) is passed should also be noted. The magnitude at maximum is stated by Gore as 7·6 and that at minimum as $<$ 9·7.

A. FOWLER.

DR. PETERS'S STAR CATALOGUE.—The case of Dr. Peters against Mr. Borst, with reference to the possession of the Clinton catalogue, containing over 30,000 stars arranged in the order of their right ascension, has been definitely settled. It will be remembered that Mr. Borst claimed the catalogue on the grounds that most of the computations had been made by him outside of his labours at the Observatory, and not under the direction of Dr. Peters, who, however, devised the work, and regarded it all

along as his own, since it included his observations extending over very many years. The court held, firstly, that the manuscript could not belong to Hamilton College, of which Dr. Peters is Professor, nor to Litchfield Observatory, of which he is Director, but to the authors and to them alone; and secondly, that the whole of the manuscript, numbering 3572 pages, held by Mr. Borst, had been wrongfully detained, and would have to be delivered to Dr. Peters, with compensation for the detention.

LONGITUDE OF MOUNT HAMILTON.—A telegraphic determination of the longitude of Mount Hamilton has been made by the United States Coast and Geodetic Survey, and the result found for the transit house meridian (Fauth transit instrument) of the Lick Observatory is—

8h. 6m. 34·807s., or 121° 38′ 42″·10 W. of Greenwich,

with an estimated probable error ± 0·1s. or 1″·5.

COMET BORELLY, *g* 1889 (DECEMBER 12).—The following elements and ephemeris have been computed for this comet by Drs. Zelbr and Froebe (*Astr. Nach.*, 2943):—

T = 1890 January 27·7438 Berlin Mean Time.

$$\left.\begin{aligned}\pi &= 211\ 4\ 23\\ \Omega &= 16\ 59\ 17\\ \iota &= 59\ 56\ 56\end{aligned}\right\}\text{Mean Eq. 1889·0.}$$

$$\log q = 9·45755$$

$$\Delta\lambda \cos\beta = -\ 4''·1$$

$$\Delta\beta = +\ 10·7$$

Ephemeris for Berlin Midnight.

1889–90.	R.A. h. m. s.	Decl. ° ′	Brightness.
Jan. 4	18 31 40	+ 21 36·2	3·68

Brightness at discovery = 1.

THE SOLAR ECLIPSE.—Intelligence has been received by Mr. Turner, Secretary of the Eclipse Committee, from Mr. Taylor, stationed at Loanda, announcing that he has obtained no observations.

ACCUMULATIONS OF CAPITAL IN THE UNITED KINGDOM IN 1875–85.

AT a meeting of the Royal Statistical Society on December 17, Mr. Robert Giffen read a paper on accumulations of capital in the United Kingdom. He began by stating that he proposed to continue and expand the paper which he read to the Society ten years ago, on "Recent Accumulations of Capital in the United Kingdom," which dealt specially with the increase of capital between 1865 and 1875. He would now deal with the accumulations between 1875 and 1885, another ten years' period, and 1885 also being practically the present time, there being very little change in the income-tax assessments since 1885, though it appeared likely enough there would be considerable changes in a year or two. His notes had extended so much, as really to become a book, which would be published immediately by Messrs. George Bell and Sons, under the title of "The Growth of Capital," and the paper he now proposed to read consisted of extracts from that book. It must be understood that the computations were necessarily very rough and approximate only, and only designed, in the absence of better figures, to throw light on the growth of societies in wealth, and on the relations of different societies in that respect, with reference to such questions as the relative burden of taxation and national debts, the rate of saving in communities at different times, and the like. Exact figures were impossible, but approximate figures were still useful. The method he followed was to take the income-tax returns, capitalise the different descriptions of income from property there mentioned at so many years' purchase, and make an estimate for property of other kinds not coming into the income-tax returns. Formerly, in comparing 1865 and 1875, he had capitalised at the same number of years' purchase in each year, but between 1875 and 1885 there were changes in capital value irrespective of changes in income which it was important to take notice of, at least as between different descriptions of property, though the results in the aggregate would not be much different from what they are if no change in the number of years' purchase were made. In 1885, then, the total valuation of the property of the United Kingdom, according to the method followed in the paper, came to 10,000 millions sterling in round figures, equal to about £270 per head. The principal items were: Lands, 1691 millions; houses, £1,927,000; railways in United Kingdom, 932 millions; miscellaneous public companies in Schedule D, 696 millions; trades and professions in Schedule D, 542 millions: farmers' profits, &c., in Schedule B, 522 millions; public funds (excluding home funds), 528 millions; gasworks, 126 millions; waterworks, 65 millions; canals, docks, &c., 71 millions; mines and ironworks, 39 millions. These were all based on the method of capitalising income in the income-tax returns, and the principal item of other property, for which an estimate was made in a different way, was that of movable property not yielding income, *e.g.* furniture of houses, works of art, &c., which was taken at about half the value of houses, or 960 millions. Comparing these figures with those of 1875, when the valuation was 8500 millions, the apparent increase was 1500 millions, or about 17½ per cent.; but there were important changes in detail, lands having declined considerably, mines and ironworks having also declined, and there being a great increase in houses and some other items. It appeared also that the increase in the decade 1875–85 was considerably less than in the previous decade dealt with in the former paper. In 1865–75, in fact, the increase was from about 6100 millions to 8500 millions, or no less than 2400 millions, and 40 per cent. in ten years, and 240 millions per annum; whereas in 1875–85 the increase was only 1500 millions, or 17½ per cent. in ten years, and only 150 millions per annum. The difference in the rate of growth was ascribed very largely to a difference in the rate of growth of money values only, reasons being given for the belief that in real prosperity, in the multiplication of useful things, and not merely money values, the improvement in the later period was not less than in the first. The distribution of this great property between England, Scotland, and Ireland, could not be exactly shown, part of the income belonging to the community of the United Kingdom in a way which did not permit of a distinction being made; but upon a rough estimate it appeared that England was considered to have 8617 millions, or 86 per cent. of the total; Scotland, 973 millions, or 9·7 per cent.; and Ireland, 447 millions, or 4·3 per cent. These figures worked out about £308, £243, and £93 per head respectively, as compared with the average of £270 for the United Kingdom. The small relative amount of property in Ireland was commented upon, and the difference between it and Great Britain was ascribed very largely to the political agitation in Ireland, which depreciated property, and the excess of population on the land, which had the same effect; these two causes together making a difference of 200 millions in the apparent capital of Ireland. Measured by property, Ireland was enormously over-represented in the Imperial Parliament. Looking at the subject historically, they found that there had been an enormous and continuous advance in the course of the past three centuries, during which at different times there had been contemporary estimates on the subject. In 1600 the property estimate was for England only 100 millions, or £22 per head; 1680, 250 millions, or £46 per head; 1690, 320 millions, or £58 per head; 1720, 370 millions, or £57 per head; 1750, 500 millions, or £71 per head; and in 1800, 1500 millions, or £167 per head. The estimate for Great Britain in the latter year being about one-eighth more in the aggregate than for England only, and £160 per head. Since 1800 there are figures for the United Kingdom, and these show: 1812, 2700 millions, or £160 per head; 1822, 2500 millions, or £120 per head (a reduction largely due to fall of prices); 1833, 3600

millions, or £144 per head; 1845, 4000 millions, or £143 per head; 1865, 6000 millions, or £200 per head; 1875, 8500 millions, or £260 per head; and finally, the present figures of 10,000 millions, or £270 per head. There was in fact a steady increase, with the exception of the interval between 1812 and 1822, when there was a heavy fall of prices, and this increase, it was believed, represented almost all through a real increase in things, money prices at any rate being at a lower rate now than at the beginning of the century. There had also been a remarkable change all through in the proportions of different descriptions of property. Lands, at the commencement constitute about 60 per cent. of the total; at the beginning of the century they are still about 40 per cent.; at the present time they are 17 per cent. only. Houses, on the other hand, are about 15 per cent. of the total at the beginning, and 19 per cent. at the present time, an increasing percentage of an ever-increasing total; but the main increase after all is in descriptions of property which are neither lands nor houses. After referring to the accumulations of capital in foreign countries, Mr. Giffen concluded by giving illustrations of the mode of using such figures, showing the difference of the burden of taxation and national debts in England, France, and the United States; the preponderance of England in the United Kingdom as compared with England, Scotland, and Ireland; the rapid growth of the United States in recent years as compared with the United Kingdom, and especially as compared with France (the national debt in the United States, from amounting twenty years ago to a sum equal to a fifth of the total property, having come to be only equal to a thirtieth of the property); and the small proportion of the annual savings of the country which comes into the public market for investment, as compared with the savings invested privately as they are made. In passing, a reference was made to the talk of the vast expenditure on military armaments, and the burden they impose on certain communities; and it was suggested that, heavy as the burdens are, yet the vast amount of property relatively indicated that the point of exhaustion was more remote than was commonly supposed. In conclusion, the hope was expressed that the discussion of recent years would lead in time to the production of better figures, especially with regard to the growth of different descriptions of property. Were trouble taken, results might be arrived at which would be of value to the Government practically, as well as to economists in their discussions. The progress of revenue was intimately connected with the progress of national resources, and the progress of money revenue with the progress of the money expression of those resources. The resources themselves, and the money values, must be studied by Chancellors of the Exchequer with almost equal anxiety, and they should both, at any rate, be studied together. Periodical complete valuations of property were in this view as indispensable as the census of population itself.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

UNIVERSITY COLLEGE, LIVERPOOL.—The Sheridan Muspratt Chemical Scholarship, of the value of £50 per annum for two years, has been awarded to Mr. J. T. Conroy, who has been a student in the chemical laboratories during the past two years. Mr. Conroy has recently taken the degree of B.Sc., with honours in chemistry, at the University of London. The Scholarship, which is the gift of Mrs. Sheridan Muspratt, is intended to enable the holder to continue work in the higher branches of chemistry. The Sheridan Muspratt Exhibition of £25 has been awarded to Mr. A. Carey, of Widnes, who has been a student of the College during the last two and a half years, and is now in the final stage of preparation in the honours school of chemistry of Victoria University.

SCIENTIFIC SERIALS.

Rendiconti del Reale Istituto Lombardo, November.—On the antidotes of the virus of tetanus, and on its prophylactic surgical treatment, by Prof. G. Sormani. In continuation of his previous paper on this subject, the author here describes some further experiments with alcohol, chloroform, and various preparations of camphor, chloral, and iodine. He finds that camphor and camphorated alcohol produce no effect on the virus, and that chloroform and hydrated chloral have a more or less attenuating action, checking the development of the artificially cultivated microbe, or even in some cases rendering it absolutely sterile, while camphorated chloral has a decidedly neutralizing effect on the virus. Other experiments show that when tetanus is once developed in the system iodoform is powerless to arrest its progress, but is most efficacious in neutralizing the virus of the injured part. The whole series of experiments fully confirms the author's previous conclusion that iodoform is the specific *disinfectant* of the microbe of tetanus.

Bulletin de l'Académie Royale de Belgique, October 12.—Jupiter's north equatorial band, by M. F. Terby. The author describes in detail the structure of this remarkable phenomenon which he has been carefully studying for the last three years with a Grubb 8-inch telescope.—Determination of the invariant functions or forms comprising several series of variants, by M. Jacques Deruyts. In continuation of his previous communications, the author here extends to forms with several series of variants the results already made known for forms with a series of *n* variables.—M. C. Vanlair describes the symptoms and treatment of a new case of bothriocephaly in Belgium, due to the presence of *Bothriocephalus latus* in the patient.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 5, 1889.—"Researches on the Chemistry of the Camphoric Acids." By J. E. Marsh.

An account is given of some experiments leading to the production, in any desired quantity, of a new camphoric acid, and to the mutual conversion of one acid into the other; as well as to a method of quantitatively separating the two acids when mixed. The space at our disposal does not permit us to enter into any details of the experiments, nor into the theoretical considerations involved. For this, reference must be made to the original paper.

December 19, 1889.—"On the Steam Calorimeter." By J. Joly, M.A. Communicated by G. F. Fitzgerald, F.R.S., F.T.C.D.

The theory of the method of condensation has been previously given by the author in the Proceedings of the Royal Society, vol. 41, p. 352.

Since the publication of that paper a much more extended knowledge of the capabilities of the method has been acquired, which has led to the construction of new forms of the apparatus, simple in construction and easily applied. Two of these are described and illustrated, one of which is new in principle, being a differential form of the calorimeter. The accuracy of observation attained by this latter form is so considerable that it has been found possible to estimate directly the specific heats of the gases at constant volume to a close degree of accuracy.

An error incidental to the use of the method arising from the radiation of the substance, when surrounded by steam, to the walls of the calorimeter, is inquired into. It is shown that this affects the accuracy of the result to a very small degree, and is capable of easy estimation and elimination.

Further confirmation of the accuracy of the method is afforded in a comparison of experiments made in different forms of the steam calorimeter.

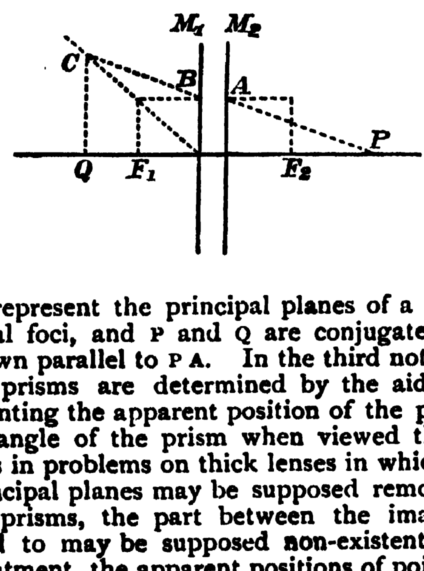
Various tables of constants are given to facilitate the use of the method, and the results of experiments on the density of saturated steam at atmospheric pressures, made directly in the calorimeter, are included. These are concordant with the deductions of Zeuner, based on Regnault's observations on the properties of steam, and were undertaken in the hope of affording reliable data on which to calculate the displacement effect on the apparent weight of the substance transferred from air to steam.

The communication is intended to provide a full account of the mode of application of the steam calorimeter.

Royal Meteorological Society, December 18, 1889.—Dr. W. Marcet, F.R.S., President, in the chair.—The following papers were read:—Report of the Wind Force Committee on the factor of the Kew pattern Robinson anemometer. This has been drawn up by Mr. W. H. Dines, who has made a

large number of experiments with various anemometers on the whirling machine at Hersham. Twelve of these were made with the friction of the Kew anemometer artificially increased, seven with a variable velocity, and fourteen with the plane of the cups inclined at an angle to the direction of motion. In discussing the results the following points are taken into consideration, viz. the possibility of the existence of induced eddies, the effect of the increased friction due to the centrifugal force and gyroscopic action, and the action of the natural wind. The conclusion that the instrument is greatly affected by the variability of the wind to which it is exposed seems to be irresistible, and if so, the exact value of the factor must depend upon the nature of the wind as well as upon the mean velocity. There is evidence to show that during a gale the variations of velocity are sometimes of great extent and frequency, and there can be but little doubt that in such a case the factor is less than 2·15. The one point which does seem clear is, that for anemometers of the Kew pattern the value 3 is far too high, and consequently that the registered wind velocities are considerably in excess of the true amount.—On testing anemometers, by Mr. W. H. Dines. The author describes the various methods employed in the testing of anemometers, points out the difficulties that have to be encountered, and explains how they can be overcome.—On the rainfall of the Riviera, by Mr. G. J. Symons, F.R.S. The author has collected all the available information respecting rainfall in this district, which is very scanty. He believes that the total annual fall along the Riviera from Cannes to San Remo is about 31 inches, and that any difference between the several towns has yet to be proved.—Report on the phenological observations for 1889, by Mr. E. Mawley. This is a discussion of observations on the flowering of plants, the appearance of insects, the song and nesting of birds, &c. Taken as a whole, 1889 was an unusually gay and bountiful year.

Physical Society, *Dec.* 6, 1889.—Prof. Reinold, President, in the chair.—The following communications were read:—On the electrification of a steam jet, by Shelford Bidwell, F.R.S. The author showed that the opacity of steam issuing from a nozzle is greatly increased by bringing electrified points near it, and that its colour is changed to orange-brown. Electrified balls and disks when placed in the steam produce similar effects, and when these are connected with an influence machine at work, the decoloration of the jet rapidly responds to each spark. On examining the absorption spectrum of the unelectrified jet, little or no selective absorption was detected, but on electrification, the violet disappeared, the blue and green were diminished, and the orange and red remained unchanged. From these results the author concludes that electrification causes an increase in the size of the water particles in the steam, from something small compared with the wave-length of light, to about 1/50000 of an inch in diameter. Allied phenomena with water jets have been observed by Lord Rayleigh, who found that a straggling water jet is rendered much more coherent by bringing a rubbed stick of sealing wax near it. These observations are of considerable meteorological interest, for the steam jet phenomena go far towards explaining the cause of the intense darkness of thunderclouds, and of the lurid yellow light with which that darkness is frequently tempered. After making his experiments the author learnt that similar observations had recently been made by the late Robert Helmholtz, who viewed the steam jets by reflected light against a dark background. On electrification the jets became much better defined, and presented diffraction colours. Luminous flames also produced similar effects, and Mr. Bidwell has found that glowing touch paper is equally efficient. Helmholtz conjectures that the sudden condensation may be due to molecular tremors or shock imparted by the electrification upsetting the unstable equilibrium of the supersaturated vapour, just as a supersaturated saline solution is suddenly crystallized when disturbed. Another hypothesis suggests that condensation is caused by the introduction of solid matter into the jet by the exciting cause, thus producing nuclei upon which the vapour may condense. On reading Helmholtz's paper, the author tried the effect of gas-flames on water jets, and found that when luminous they influenced the jet considerably, whereas non-luminous flames had no appreciable effect. He also found that luminous flames are positively electrified, and demonstrated this before the meeting. Prof. Rücker thought the surface tension of the films surrounding the water jets might be lowered by the presence of a burning substance, and that the smoke from the touch paper used in some of the experiments on steam jets would introduce solid particles and facilitate condensation. Mr. Richardson inquired whether a red-hot iron had any effect. Dr. Fison said he had made experiments on the electrification of flame, and found that potentials varying from + 2 volts to − 1½ volts could be obtained in the region within and surrounding a Bunsen flame. Prof. S. P. Thompson commented on the contrast between Mr. Bidwell's experiments and those of Dr. Lodge on the dissipation of fogs by electricity, and also asked whether the colour of the jet depended on the length of the spark produced by the machine. Prof. Forbes thought a crucial test between the two hypotheses of Helmholtz could be obtained by trying the experiment in a germless globe. The President said he had recently noticed that gas flames were electrified. Mr. Bidwell in reply said he ought to have mentioned that the effect of flames on jets may be due to dirt, for if soap or milk be added to the water in the steam generator, no effect is produced by electrification or flame. As to change of colour with spark-length, little (if any) variation is caused thereby. He had not tried whether a red-hot iron produced any effect on a steam jet.—Notes on geometrical optics, Part 2, by Prof. S. P. Thompson. Three notes were presented, the first of which dealt with the geometrical use of "focal circles" in problems relating to lenses and mirrors, and to single refracting surfaces. By "focal circles" the author means the circles having the principal foci as centres, and whose radii are equal to the focal lengths. By their use the point conjugate to any point on the principal axis is readily determined. One construction for a mirror is to draw a tangent to the focal circle from a point P on the axis; the foot of the perpendicular to the axis drawn through the point of contact gives the point conjugate to P. When applied to a thin lens, a tangent is drawn as above to one focal circle, and the line joining the point of contact with the centre of the lens is produced to meet the other focal circle; a perpendicular to the axis from the remote point of intersection gives the conjugate point. Modifications applicable to thick lenses and single refracting surfaces were also given. In his second note the author treated similar problems by the aid of squares drawn on the principal focal distances, the constructions being remarkably simple, as will be seen from the figure, in



which M_1 M_2 represent the principal planes of a thick lens, F_1, F_2, its principal foci, and P and Q are conjugate points. The line BC is drawn parallel to PA. In the third note, the paths of rays through prisms are determined by the aid of imaginary planes representing the apparent position of the plane bisecting the dihedral angle of the prism when viewed through its two faces. Just as in problems on thick lenses in which the part between the principal planes may be supposed removed, so when dealing with prisms, the part between the imaginary planes above referred to may be supposed non-existent. In another method of treatment, the apparent positions of points outside the prism when viewed from inside the prism are made use of, and their application to illustrate dispersion was pointed out. Mr. C. V. Boys asked whether the latter construction could be used to show why the slit of a spectroscope appears curved.—On the behaviour of steel under mechanical stress, by Mr. C. H. Carus-Wilson. This is an inquiry into the properties of steel as illustrated by the *stress-strain* curves given in automatic diagrams from testing machines, and by magnetic changes which take place during testing. After pointing out that the permanent elongation of a bar under longitudinal stress consists of a sliding combined with an increase of volume, the author showed that the "yield" is caused by the limit of elastic resistance (ρ) parallel to one particular direction in the bar (generally at 45° to the axis) being less than along any other direction. When this lower limit is reached, sliding takes place in this direction until the hardening of the bar caused thereby raises the limit of elastic resistance (in the direction referred to) to that of the rest of the bar, after which the stress must be increased to produce further permanent set. From considerations based on the stress-

strain curves of the same material when hardened to different degrees by heating and immersion, &c., it was concluded that the increase of (ρ) during "yield" is the same for all the specimens, and that the "yield" is a measure of the "hardness." The question of discontinuity of the curves about the "yield point" was next discussed, and evidence to the contrary given by specimens which show conclusively that the yield does not take place simultaneously at all parts of the bar, but travels along the bar as a strain wave. In these specimens the load had been removed before the wave had traversed the whole length; and the line between the strained and unstrained portions could be easily recognized. As additional evidence of continuity, the close analogy between the *stress-strain* curves of steel of various degrees of hardness, and the isothermals of condensible gases at different temperatures when near their point of liquefaction, was pointed out; the apparent discontinuity in the latter probably being due to the change from gas to liquid taking place piecemeal throughout the substance (see Prof. J. Thomson, Proc. Roy. Soc., 71, No. 130). In seeking for an explanation of the hardening of steel by permanent strain, the author was led to believe this due to the displacement of the atoms within the molecules of the substance. To test this hypothesis, experiments on magnetization by stretching a bar in a magnetic field were made; these show that the magnetization increases with the stress up to the "yield point," and is wholly permanent when approaching that point. On comparing his results with Joule's experiments on the elongation of loaded wires produced by magnetization, the author infers that there are two kinds of elongation—firstly, that produced by relative motion of the molecules, and secondly, an elongation resulting from a straining of the molecules themselves. To this latter straining the hardening by permanent strain is attributed, and this view seems compatible with the results of Osmond's researches on the hardening of steel.—Mr. F. C. Hawe's paper was postponed.

Mathematical Society, Dec. 12, 1889.—Mr. J. J. Walker, F.R.S., President, in the chair.—The following papers were read:—On the radial vibrations of a cylindrical elastic shell, by A. B. Basset, F.R.S.—Note on the 51840 group, Dr. G. G. Morrice.—The President then vacated the chair, which was taken by Mr. E. B. Elliott, Vice-President.—Complex multiplication moduli of elliptic functions for the determinants -53 and -61, by Prof. G. B. Mathews (communicated by Prof. Greenhill, F.R.S.).—On the flexure of an elastic plate, by Prof. H. Lamb, F.R.S.—Notes on a plane cubic and a conic, by R. A. Roberts (communicated by the Secretary).—Dr. Larmor and Mr. Curran Sharp made brief communications.

Edinburgh.

Royal Society, December 16, 1889.—Sir Arthur Mitchell, Vice-President, in the chair.—Dr. Thomas Muir read a note on Cayley's demonstration of Pascal's theorem. He has succeeded in simplifying the proof.—Dr. Muir also read a paper on self-conjugate permutations, and one on a rapidly converging series for the extraction of the square root.—Prof. Tait read a note on some quaternion integrals, and also a note on the glissette of a hyperbola. When a given ellipse slides on rectangular axes, any point in its plane traces out a definite curve, and the same curve can be similarly obtained as the trace of a definite point in the plane of a certain hyperbola sliding between axes in general inclined to the former.—Dr. Woodhead communicated a paper, written by Dr. Herbert Ashdown, on certain substances, formed in the urine, which reduce the oxide of copper upon boiling in the presence of an alkali. Dr. Ashdown was led to search for these substances in the human subject as the result of observations made upon lower animals.—Dr. G. E. Cartwright Wood discussed enzyme action in the lower organisms.—Dr. Woodhead communicated a paper, by Mr. Frank E. Beddard, on the structure of a genus of Oligochætæ belonging to the Limnicoline section.

Paris.

Academy of Sciences, December 16, 1889.—M. Hermite in the chair.—Note on the eclipse of December 22, by M. J. Janssen. The arrangements are described which were made at the Observatory of Meudon for observing this event.—On the effects of a new hydraulic engine used for irrigation purposes, by M. Anatole de Caligny. The general disposition of this apparatus was fully described in the *Comptes rendus*, November 19, 1887. The present note has reference to an improvement introduced for the purpose of remedying a serious defect in the original design. It has now the advantage of giving as good results as any of the systems in general use, while superior to them in simplicity and economy.—On the production of films of ice on the surface of the alburnum of certain species of plants, by M. D. Clos. Early in December, after a hard frost, when the glass fell to $-6°$ C. at night, *Verbesina virginica*, *Helianthus orgyalis*, and several other plants exhibited the same phenomenon of glaciation at the Toulouse Botanical Garden as was observed and described by Dunal at Montpellier in 1848. An explanation is here given of the phenomenon, which occurred on a much larger scale on the present than on the previous occasion.—Observations of Borrelly's new comet (*g* 1889), made at the Paris Observatory with the equatorial of the west tower, by M. G. Bigourdan. The observations were taken on December 15, when the comet presented the appearance of a nebulosity indistinctly round, of 2′ diameter, slightly more brilliant in the central region, but without notable condensation. In its expanse were clearly visible two stellar points, and the presence of several others suspected.—On the series $\sum\frac{1}{k^2}$, $\sum\frac{1}{k^3}$, by M. André Markoff. From the nature of these series the author establishes a formula which yields the equation—

$$1 + \frac{1}{2^3} + \frac{1}{3^3} + \frac{1}{4^3} + \ldots = 1{\cdot}202\,056\,903\,159\,594\,285\,40,$$

correct to 20 decimals. M. Markoff's paper forms a sequel to Stirling's memoir "De Summatione et Interpolatione Serierum Infinitarum."—On magnetic potential energy and the measurement of the coefficients of magnetization, by M. Gouy. The mechanical action of magnets on isotropous substances, diamagnetic or feebly magnetic isotropous bodies, has often been utilized for measuring or comparing the coefficients of magnetization assumed to be constants. On this hypothesis has been established the expression of the potential energy which serves to calculate the mechanical action in question. Here M. Gouy proposes to supply a somewhat more complete theory by regarding these coefficients, not as constants, but as variable with the magnetizing force, and utilizing the experimental data for measuring the variations.—On the colour and spectrum of fluorine, by M. Henri Moissan. The colour of fluorine as here determined is a greenish-yellow, much fainter than that of chlorine under like conditions, and inclining more to the yellow tint. Thirteen rays have been determined in the red region of the spectrum. With hydrofluoric acid several bands have been obtained in the yellow and violet, but very wide and not sufficiently distinct to fix their position with accuracy.—Action of ammonia on the combinations of the cyanide with the chlorides of mercury, by M. Raoul Varet. The paper deals severally with the action of ammonia on the cyanochloride of mercury; the action of absolute ammoniacal alcohol; the action of ammoniac gas; the cyanochloride of mercury and zinc; and the cyanochloride of mercury and copper.—On an adulteration of the essence of French turpentine, by M. A. Aignan. This fraud, which consists in the addition of a small quantity of the oil of resin, is not easily detected, but may be discovered by studying the rotatory power of the liquid, as is here shown.—Papers were submitted by M. Besson, on the temperature of solidification of the chlorides of tin and arsenic, and on their faculty of absorbing chlorine at a low temperature; by M. Seyewitz, on the synthesis of dioxidiphenylamine and of a red-brown colouring substance; by M. Pierre Mercier, on a general method of colouring photographic proofs with the salts of silver, platinum, and the metals of the platinum group; and by MM. G. Pouchet and Biétrix, on the egg and first development of the alose, a fish allied to the sardine.

December 23.—M. Hermite in the chair.—On the discovery of a fossil ape, by M. Albert Gaudry. On presenting to the Academy the skull of an ape recently discovered by Dr. Donnezan at Serrat d'en Vaquer, M. Gaudry remarked that, except those from Pikermi in Greece, these are the only cranial remains of a fossil Simian hitherto brought to light. Many other fossils have been found in the same place, which evidently contains large accumulations, especially of extinct vertebrate animals.—Observations of the comet discovered by M. Borrelly at the Observatory of Marseilles, on December 12, by M. Stephan. The observations are for December 12, 13, and 14, during which period the comet steadily increased in brightness, and assumed more distinct outlines. On the 12th it was

obscured for a few minutes by a star of the tenth or eleventh magnitude.—Determination of the difference of longitude between Paris and Leyden, by M. Bassot. This international operation, executed by MM. Van de Sande Bakhuyzen and Bassot, presents a special geodetic interest, Leyden being the northernmost station of the meridian of Sedan which now passes through Belgium far into the Netherlands. From the observations the difference of longitude between Paris and Leyden appears to be 8m. 35·602s., with probable error ± 0·011s., which, reduced to the official meridians, gives 8m. 35·213s.—On the degree of accuracy attained by thermometers in the measurement of temperatures, by M. Ch. Ed. Guillaume. On presenting to the Academy his "Traité pratique de la Thermométrie de précision," the author took occasion to reply to M. Renou's recent remarks on the accuracy of the mercury thermometer. Reviewing the whole question, and comparing the opinions and experiences of the most distinguished physicists during late years, M. Guillaume considers it placed beyond doubt that mercury thermometers with glass of varying qualities yield varying results. But these differences, formerly supposed to be fortuitous, are now known to be systematic, so that any number of instruments giving identical results may be constructed by a judicious selection of glass and careful manipulation.—On β-inosite, by M. Maquenne. In a previous note (*Comptes rendus*, vol. cix. p. 812) the author showed that pinite may be decomposed into a molecule of methyl iodide and a molecule of a new sugar called by him β-inosite. The analysis of these two bodies leading to identical results, he inferred that they were isomerous, presenting relations of the same order as those existing between the two known hexachlorides of benzine. This hypothesis has been fully confirmed by his further study of β-inosite, communicated in the present memoir.—On a new class of diacetones, by MM. A. Béhal and V. Auger. The authors have already shown that the chlorides of malonyl, methylmalonyl, and ethylmalonyl react on the aromatic carburets, yielding diacetones, β,R—CO—CHX—CO—R. They have also determined the formation of compounds having the characteristic property of yielding with the alkalies and alkaline carbonates blood-red solutions. A further series of researches has now enabled them to prepare several of these compounds in large quantities, and thus study their constitution as here described. The best results were yielded by metaxylene and the chloride of ethylmalonyl.—Optical properties of the polychroic aureolas present in certain minerals, by M. A. Michel Lévy. This curious phenomenon is traced mainly to the presence of small crystals of zircon widely disseminated throughout granitic and other rocks. In some cases it may also be due to the presence of dumortierite and allanite. These aureolas offer an interesting example of a simultaneous modification of birefraction and polychroism, a modification, however, which is not permanent, or at least which may disappear, without involving any change in the properties of the mineral itself.—Analysis of the Migheï meteorite, by M. Stanislas Meunier. This meteorite, which fell on June 9, 1889, at Migheï, in Russia, yielded besides the usual constituents, a new element, which M. Meunier has not yet succeeded in identifying.—Papers were contributed by M. Y. Wada, on the earthquake of July 28 at Kiushu Island, Japan; by M. Ch. Contejean, on the circulation of the blood in mammals at the moment of birth; by M. Ferré, on the semeiologic and pathologic study of rabies; and by Messrs. Woodhead and Cartwright Wood, on the antidotic action exercised by the pyocyanic liquids on the development of the anthracite disease.

BERLIN.

Meteorological Society, Dec. 3, 1889.—Dr. Vettin, President, in the chair.—Dr. Kremser spoke on the frequency of occurrence of mist, a subject whose investigation he had recently undertaken. Up to the present time the material derived from observation is extremely scanty, as shown by the extremely divergent mean values obtained for different places in close proximity to each other, as, for instance, Hamburg and Altona, or even different parts of the one city, Berlin. It seems scarcely possible to attribute the differences to local conditions in all cases, for the mean annual values resulting from the observations of different observers in one and the same place show an equally striking discordancy. This is undoubtedly due to the want of suitable units for estimating and measuring mists. From the above it follows that it is impossible to determine any secular changes on the basis of existing observations, although the yearly variations may be. By comparisons based on a long series of observations, it appeared that a series extending over ten years suffices to give a reliable monthly mean. From this it appears that at most stations the maximal amount of mist occurs in the months of November and December, the maximum occurring in November in the eastern provinces of Prussia, and falling progressively later the further the stations lie towards the west. On the coasts of the North Sea and on the adjacent islands the maximum is observed in January, while it occurs on mountains as early as September and October. At the latter stations the minimum is met with as early as May, and is progressively later (June and July) at the other stations according to the lateness of the maximum. On the islands, as, for instance, Heligoland, the minimum does not occur before September or October. As a general rule, 70 per cent. falls in autumn and winter, 20 per cent. in spring, and 10 per cent. in summer. The amplitude of the yearly differences is greatest on the plains and least on mountains. The number of days on which mist occurs is greatest at mountain stations, amounting on the average to 200 per annum, falling in the low lands to as few as 40 or less. The material at hand for determining the variations in the amount of mist per diem was extremely scanty; still it was possible to make out that, in winter, mist is most frequent in the morning, diminishing considerably towards midday, and being in the evening at times as frequent as at midday, at times somewhat more frequent. In summer, mist is observed only in the morning, and then disappears completely. In the discussion which followed the above communication it was pointed out how essential it is to distinguish between clouds and mist, as also many other factors, such as the frequency of purely local mists, the absence of wind, the difficulty of determining the density of mists, the differences of altitude, &c.—Dr. Sprung spoke on some new self-recording apparatus of various kinds made by Richard of Paris, and described fully his actinometer and anemocinometer.

Physical Society, Dec. 6, 1889.—Prof. Kundt, President, in the chair.—Prof. Planck spoke on the development of electricity and heat in dilute electrolytic solutions. From the experiments of Kohlrausch and Hittorf, and the theoretical considerations of Van t' Hoff, Arrhenius, and Nernst, all that takes place in dilute electrolytic solutions during the passage of a current is very accurately known, especially in the cases where the solution is very dilute and the electrolyte is very uniformly distributed in it. It has become possible to subject the occurrences in electrolytic solutions to mathematical investigation, owing to the existing conceptions of the osmotic pressure in such solutions, of the more or less complete dissociation of the electrolyte when in dilute solution, of the applicability of the gaseous laws to such solutions, and owing to the experimental determination of the rate at which the *ions* travel. The speaker had submitted the general case, in which the solution is not quite uniform, to a mathematical analysis, and deduced the formulæ which represent that which is taking place in each unit of volume of the highly diluted solutions in which dissociation is complete. These formulæ correspond exactly to those arrived at by Nernst for the development of electricity. Up to the present time the thermal phenomena in dilute electrolytic solutions have not been fully dealt with. The speaker showed that heat is the most important form of energy existing in the solution. It is only possible to arrive at a complete understanding of the heat production if, when drawing parallels between dilute solutions and gases, a further step is taken, and it is assumed that just as gases become warmer by compression and colder by a fall of pressure, so also heat is developed in electrolytic solutions when the *ions* are increased in number, and disappears when they are diminished per unit of volume. Hence the mere diffusive processes in an electrolytic solution whose composition is not uniform must develop an osmotic heat, which makes its appearance, and can be calculated in the absence of any electrical current. This osmotic heat must be taken into account, along with the two already known sources of heat production, during the passage of an electric current through a solution, before it is possible to calculate all the relationships of energy in a dilute, non-uniform, electrolytic solution during the passage of a current through it.—The President exhibited the air-pump constructed by Otto von Guericke in 1675, which had recently been acquired by the Physical Society. This pump is still in a thoroughly workable condition, with the exception of the glass vessel, which has been renewed. The pressure in this receiver could be reduced to 20 mm. of mercury, by means of the pump. The

celebrated Magdeburg hemispheres have also come into the possession of the Society, and were exhibited at the same time; they are perfect except in the want of the leather packing.

AMSTERDAM.

Royal Academy of Sciences, November 30, 1889.—Dr. Hoek read a paper on the Zuyder Zee herring, showing that it belongs to a race of spring herrings (herrings spawning in spring) closely related to the spring herrings of the Baltic, as described by Heincke. But whereas, in the Baltic, two races of herrings—an autumn or winter herring, and a spring herring—can be distinguished, all the herrings which enter the Zuyder Zee—both those which enter it in autumn and those which are caught in spring—belong to one variety: they all spawn in the spring months only; they are reproduced only in water that is rather brackish (nearly fresh); and their fry is very small in comparison with that of open-sea herrings. Considering that the Zuyder Zee herring is a variety which has sprung from the open North Sea herring, it furnishes a striking instance of the formation of a variety under changed conditions in the course of a few centuries.—Prof. van de Sanden Bakhuyzen gave an account of the meeting of the Committee for the Construction of the Photographic Map of the Heavens, held at Paris in September last, and spoke about the share of the Dutch astronomers in that undertaking.

THURSDAY, JANUARY 9, 1890.

THE ZOOLOGICAL RESULTS OF THE "CHALLENGER" EXPEDITION.

Report on the Scientific Results of the Voyage of H.M.S. "Challenger" during the Years 1873–76, *under the command of Captain George S. Nares, R.N., F.R.S., and the late Captain Frank T. Thomson, R.N.* Prepared under the superintendence of the late Sir C. Wyville Thomson, Knt., F.R.S., &c., Director of the Civilian Staff on board, and now of John Murray, LL.D., Ph.D., &c., one of the Naturalists of the Expedition. Zoology—Vols. XXXI. and XXXII. (Published by Order of Her Majesty's Government. London: Printed for Her Majesty's Stationery Office, and sold by Eyre and Spottiswoode, 1889.)

WITH these recently published volumes, the series of Reports on the zoological results of the *Challenger* Expedition, comes to a close. Volume XXXI. contains three Reports, the first of which is on the "Alcyonaria," by Profs. E. Perceval Wright and Th. Studer. It would appear that on the first distribution of the zoological treasures of the Expedition, the Alcyonaria were given to Prof. von Kölliker to describe, and the first part of his Report on the Pennatulidæ, forms the Second Report published in 1880. From a note of the editor, we learn that Prof. Kölliker being unwilling to undertake the remainder of the group, the fixed forms were committed to Dr. E. P. Wright for description. After the appearance of the "Narrative of the Expedition" in which a few of the more remarkable of the new species were described by this author, Prof. Studer consented to join Dr. Wright in preparing the Report, and all the details were worked out in unison.

The Report opens with a brief introduction, in which an attempt is made to present a more or less complete list of the orders, families, and genera, of the recent Alcyonaria; short diagnoses and references to the bibliography are given. While this introduction might with advantage have been greatly expanded, yet we think its value will be appreciated by all those working at this group. This is followed by the description of the genera and species in the *Challenger* collection. In the earlier pages an attempt has been made to include brief notices of all the known forms, but it was soon found that this would occupy too much space, as the forms from large portions of the Indian Ocean and the very rich Alcyonarian fauna of the western shores of North America were not represented in the collection.

One hundred and eighty-nine species are described as found during the voyage of the *Challenger* and of this number no less than one hundred and thirty-three are described as new. Of the more interesting of these, the following may be mentioned, *Callozostron mirabilis*, a most extraordinary species taken in the Antarctic Sea, in the most southerly dredging made during the voyage. While there can be no doubt as to its affinities yet this form presents many puzzling features. Another remarkable species from the Fiji's, *Calypterinus allmani*, although it has a rigid axis, in the arrangement of its polyps shows some relationship to the previously mentioned species A great number of new species are added to a genus quite recently described by Verrill, and which is made the type of the family Dasygorgidæ. The new genus Acanthoisis, which is nearly related to the well known genus Isis, exhibits an unique condition of its axis, which consists of alternate horny and calcareous joints, the latter being very beautifully grooved and spined. *Keroeides koreni*, with a sclerogorgic axis, from Japan, is also a curious species, with massive spicules.

Under the heading of "Geographical Distribution," a brief history is given of the distribution of the species of most of the well-established genera; while this subject is necessarily very incomplete, yet it would seem as if the West Indian Islands, the Californian shores of America, the Australian seas and especially those of Japan were the chief centres of the group. But it cannot be overlooked that the record is very imperfect and that the recent researches of Danielssen have proved that immense numbers of species exist in the seas of Norway.

This Report extends to 386 pages and is illustrated by 49 lithographic plates, the figures in which have been drawn by Mr. George West, Jun., and Mr. Armbruster of Berne.

The second Report is by Dr. Günther, on the pelagic fishes, and comprises an account of the specimens which were obtained in the open ocean by means, chiefly, of the surface net.

The specimens were as numerous as those of either the shore or deep-sea fishes, described in the author's first and second Reports on the *Challenger* fishes, and by far the greater number were of small size; some, indeed, had been taken at so early a stage in their development as to make it impossible to refer them to their family or even order. The pelagic fish fauna, as defined by the author, consists, first, of the truly pelagic fish—those which habitually live on the surface of the ocean, accidentally and rarely approaching the shore; the majority breed in the open sea and pass through all their phases of growth without coming into the vicinity of land; numerous representatives of these were in the collections. Secondly, there are a number of fishes inhabiting the depth of the ocean, from a hundred fathoms downwards, which seem periodically to ascend to the surface, possibly in connection with their propagation; most of these are found at the surface, only during the early stages of their growth, but they connect the truly surface fishes with the deep-sea fishes, and were fairly well represented in the collection. Thirdly, the pelagic fauna receives a very considerable contingent from the littoral fauna; some shore fishes, when in a young state, are, while floating on the surface, driven to sea to great distances by currents and winds; many such immature forms were found. And, lastly, fully developed specimens of littoral species sometimes stray or are accidentally driven out to the open sea, and several such were in the collection.

Sixty-seven species are indicated, and several new genera and species are described. A new species of Branchiostoma is described from the Pacific; it was either from the surface or from a depth of 1000 fathoms; the perfect condition of its delicate fin-fringe seemed to militate against the latter idea, and yet it would be even more extraordinary to find a lancelet living at the surface

of the open sea. This Report extends to 47 pages, and has six plates.

The third Report is by Arthur W. Waters, and is entitled a "Supplementary Report on the Polyzoa.' From every point of view we regret that these "notes the time for the preparation of which has been limited by Mr. Murray," have been published as part of the present series of Reports.

If the Reports on the *Challenger* Polyzoa by the late George Busk, which form Parts XXX. and L. of the zoological series, had been defective, say, for example, that a number of new or rare species had escaped description, then it would have been useful and perhaps excusable to have had a supplemental Report issued, noting such; but out of the 41 pages of which this Supplementary Report consists, not more than one and a half are devoted to the record of the three new species described, while the rest is simply a series of criticisms on the late Mr. Busk's work.

The very heading of the Report contains an implied piece of criticism, "The term Polyzoa is used for sake of uniformity." Into the argument *pro* and *con* for the use, of this term it is not needful for us here to enter, but remembering what Mr. Busk had written to justify its use, this uncalled-for remark might have been omitted. We read:—

"Shortly after the death of Mr. George Busk, who prepared the Report on the *Challenger* Polyzoa, I had, through the kindness of his daughter, Miss Busk, an opportunity of examining some of the duplicate specimens, and I desire to thank her for sending me those which, from published criticism, were most interesting to me. I have also to thank Mr. John Murray, the director of the *Challenger* publications, for allowing me to examine the whole of the duplicate material in Edinburgh. I communicated to Mr. Murray some valuable results arising from an examination of sections of the *Challenger* specimens prepared by a method similar to that employed in the examination of fossil Polyzoa, and at his request I have drawn up the following supplementary notes on the *Challenger* species."

We have been careful to quote the author's own account of his work, which would have formed an interesting communication to any of our scientific Societies, but which seems to us to be quite out of place where it is now published. There is probably not one of the eighty-two Reports published on the zoological results of the *Challenger* Expedition that could not be added to and emended, and no one would wish that they should escape every just criticism, but this is quite a different thing from employing the funds placed by the Treasury for the publication of these Reports on the printing and illustrating of critical notes on the already published ones. This supplementary Report is illustrated by three plates from drawings of the author.

In the editorial notes to Vol. XXXII. we are told:—

"This volume concludes the zoological series of Reports on the scientific results of the Expedition, with the possible exception of a few supplementary notes to some of the memoirs and Prof. Huxley's Report on the genus Spirula, which may appear as an appendix to the concluding summary volume."

We must content ourselves with protesting against the publication of any further "supplementary notes" on the Reports unless these are contributed by the several authors thereof. As to a "concluding summary volume," opinions may differ as to the advisability of publishing a summary of the thirty-two volumes in the same series as the original volumes. For the scientific worker such a summary would be quite useless, for any such would have recourse to the full details. For the general reader, anxious to know something of the facts stored away, beyond his reach, in these many ponderous volumes, a summary would no doubt be of interest, and, if fairly well executed, of value, but the size and cost of a volume like those already published in this series would place such far beyond the buying powers of most people, and to us it would seem a waste of public money to undertake so unnecessary a labour. If, indeed, the Treasury would publish, in a convenient handy volume, a carefully prepared sketch of the cruise of the *Challenger*, with a few chapters added giving a summary of the additions to biological knowledge, which were the immediate results of the Expedition, such a volume would be acceptable to the general public, and would let them know more than they at present do of the most important voyage of discovery of this century.

The first Report in Volume XXXII. is on the Antipatharia by George Brook, and we believe it to be one of the most praiseworthy of all the Reports; the time at the disposal of the author was of necessity very short, and perhaps no group of marine animals had been so little attended to. Our Museums no doubt possessed numerous specimens, but these being in the great majority of cases, only the dried skeletons, presented little upon which to work, there were therefore many and serious drawbacks to a determination of the species or to a knowledge of their anatomy. In spite of all this Mr. Brook has succeeded in making this Report an excellent contribution to our knowledge of the classification, distribution, and anatomy of the group. There was one fortunate circumstance about the *Challenger* specimens, most of them had the polyps well preserved, so that their structure could be fairly well made out. Making the most of the material at his disposal, the author has attempted a partial revision of the group, and has placed the classification for the first time on a natural basis. The study of the fine collections made by Pourtales and during the voyages of the *Blake*, would have greatly assisted Mr. Brook's labours, but as in the case of the Alcyonaria, the specimens were not available.

Nearly all the forms collected by the *Challenger* were new, which is to be largely accounted for, by the fact that almost all the collections were made in localities from which no Antipatharia had been previously recorded. The collection is remarkably deficient in littoral forms, but a number of species are now for the first time described from great depths. In this monograph not only are all the *Challenger* species described but a number of new species in the British Museum are also described, so that the Report forms quite a monograph of the group.

The Report opens with a bibliography, not a very extensive one, and one which up to the time of Pallas, possesses little interest. Botanists like Bauhin, Tournefort, and Breynius are among the pre-Linnæan writers who refer to these corals, and it is worthy of note that the last mentioned of these authors, describes and gives an

excellent figure of a species of Antipathes, in his "Prodomus fasciculi rariorum plantarum anno 1679 in hortis celeberrimis Hollandiæ, etc., observatarum." He calls it *Abies maritima*, and mentions it as a fossil plant; thus beginning his Prodomus with a form which was not a plant, and which certainly never grew in any of the Dutch gardens. After the bibliography there is a critical review of the literature; it is pleasing to find the author doing justice to Esper's "beautiful work 'Die Pflanzenthiere,'" and without wishing to enter on any technical criticism in a general notice like this, we may mention, in reference to a remark that "Esper does not describe *Antipathes ericoides*, but gives a figure of it," that in the second volume of his work, p. 150, he tells us that the name *Antipathes myriophylla* should replace the name of *Antipathes ericoides* engraved on the plate, and having a delamarck's[1] copy of the "Fortsetzungen der Pflanzenthiere" open before us, we may add that nearly all the references to Part ii. of this work in Mr. Brook's Report should be to Part i. Part ii. contains only 48 pages, and *Antipathes virgata*, Esper, is the only species of the genus described in it. In justice to Esper it may be also mentioned that he corrects his mistake of describing a decorticated gorgonid as *A. flabellum* (*vide* "Pflanzenth. forts.," ii. Th. p. 33).

The general morphology is next treated of, a general outline of the structure of the various genera, more especially with regard to the forms of the zooids and the number of and relative development of the mesenteries; this is the first detailed outline of the kind yet published on the morphology of the group, and it is illustrated by woodcuts. The classification and description of the genera and species follow; then notes on the geographical and bathymetrical distribution. Four species were taken at depths of between 2000 and 3000 fathoms.

A chapter on the anatomy concludes the Report, but we must content ourselves with quoting only the last few words of this most valuable contribution:—

"The Antipathinæ approach the Cerianthidæ more closely than the Hexactiniæ in structure, particularly in the following points: the arrangement of the mesenteries; the relatively thin mesoglœa, which is entirely devoid of stellate connective tissue cells; the presence of an ectodermal muscular layer in the stomodæum and body wall; and the rudimentary condition of the musculature of the mesenteries."

This Report extends to 222 pages, and has an atlas of 15 plates.

The second Report in this volume is by Prof. Th. Studer, M.D. Bern, being a "Supplementary Report on the Alcyonaria." We quote the short preface:—

"After the main Report on the *Challenger* Alcyonaria was in the press, several further specimens were found. These were in part new species, of which however, it was no longer possible to insert a description in the text. I am under great obligations to Dr. John Murray, the editor of the *Challenger* Reports, for allowing me to publish in the form of a supplement an account of these new species with the necessary illustrations. At the same time I have seized the opportunity to insert further illustrations of such forms as Dr. Wright and myself had only been able to describe in the Report, as *Telesto trichostemma* and *Siphonogorgia kollikeri*. This supplement extends the list of the *Challenger* collection by three new species of the genus Siphonogorgia, three Muriceidæ, an Indian representative of the genus Bebryce (which before had been known only from the Mediterranean), and one of the Plexauridæ."

[1] So Lamarck has written his name on the title-pages.

It seems surprising that as a matter of courtesy, quite apart from other considerations, either the editor of these Reports or the author of this supplementary one, could have brought out this 81st Part of the *Challenger* Reports, without any communication with or participation therein, by Prof. Wright, to whom the preparation of the Report of the fixed Alcyonaria was originally committed.

With personal matters the reader has no right to be troubled, but he may well inquire why, when the Report itself was published in 1889 as the joint work of two Reporters, who narrate in their preface how pleasantly they worked in unison, there should appear in the same year this supplementary Report, written by but one of the two, and why he should acknowledge "his great obligations to Dr. Murray for enabling him to describe seven new species, under his own name," which had been found not by himself, but had been transmitted to him by his co-reporter as new forms early in 1888. The dates of the reception of the manuscript of this supplement prove that it could have been easily added to the appendix to the Report.

This supplementary Report adds eight, not seven as stated in the preface as quoted above, to the species collected during the cruise of the *Challenger*. The "Indian representative of the genus Bebryce" belongs to the Muriceidæ; but the interesting *Sarakka crassa*, Dan., belonging to the Alcyonidæ must be added to the list. Seven new species are described and figured, in addition to the last mentioned species, and figures are given of *Siphonogorgia kollikeri* and *Telesto trichostemma* which were described in the original Report. To the fourteen pages of the Report is added a list of the Alcyonaria (Pennatulacea excepted) obtained during the voyage, arranged according to the order of the stations at which they occurred; this comparatively useless record occupies ten pages, and is followed by a four page account of the bathymetrical range of the species, which takes no account of the record of the ranges as given in the original Report, which omits references to some of the *Challenger* forms and alludes to a large number of genera not found by the *Challenger*.

The six plates have been well drawn by Armbruster of Berne.

The third Report and the last of the series is by Prof. Ernst Haeckel, on the deep-sea Keratosa.

It will be remarked that this is not a "supplementary" Report to the Report on the Keratosa by Dr. Poléjaeff published in 1884, and it may be mentioned that the forms herein described appear to be of a very doubtful nature, "several spongiologists (among them some well known authorities) had denied their sponge nature and declared that these peculiar objects were either Rhizopods or other Protozoa. Other naturalists on the contrary who were closely acquainted with the Rhizopods, could not acknowledge their Rhizopod nature, neither could they make out the class to which they belonged." Possibly Prof. Haeckel was even one of these later for he tells us that "A *closer* comparative examination of these doubtful

organisms of the deep sea has led me to the conviction that they are true sponges, for the most part modified in a peculiar manner by the symbiosis with a commensal organism which is very probably in most cases (if not in all) a Hydropolyp stock."

Four families and eleven genera of these strange forms are described, and the species are well illustrated. With some few of them we may have had a previous acquaintance, but these turn up here with quite new faces; for, "to avoid further confusion," the author "proposes to employ the term Haliphysema for that monothalamous Foraminifer in the sense of Mobius, Brady, and most recent authors"; while "for the true Physemaria, however," which he described in 1876 "as *Haliphysema primordialis*, &c., it will be best to adopt the term Prophysema," and he thinks that "it may be that the body-wall (in these Physemaria) is perforated by numerous microscopical pores, and that these were closed temporarily and accidentally during the few hours I was examining them; in this case they are Ammoconidæ," that is, belong to the first family of these deep-sea Keratosa.

In the truly extraordinary forms placed in the fourth family of Stannomidæ, containing specimens taken from depths of between 2425 and 2925 fathoms, we find present a fibrillar spongin skeleton, composed of thin, simple or branched spongin fibrillæ, never anastomosing or reticulated and also symbiotic Hydroids. Haeckel thinks that these "fibrillæ" throw some light on the peculiar filaments met with in the Hircinidæ, and that in both instances these fibres are not independent organisms, but are produced by the sponges, in which they occur, and should be regarded, as "monaxial Keratose spicules."

In concluding this notice of one of the most remarkable of the series of animal forms found during the expedition of the *Challenger*, we feel compelled to protest against the style of the author's criticisms on Poléjaeff's previously published Reports on the Keratosa. It is very easy to write that "the whole systematic work of Poléjaeff turns in a large *circulus vitrosus*," &c., &c., but is it fair or just for one Reporter to thus, at the expense of Her Majesty's Treasury, write of a fellow Reporter? Such sentences must have been overlooked by the editor.

This Report extends to ninety-two pages, and is accompanied by an atlas of eight coloured plates.

THE VERTEBRATES OF LEICESTERSHIRE AND RUTLAND.

The Vertebrate Animals of Leicestershire and Rutland. By Montagu Browne. Pp. 223, illustrated. (Birmingham and Leicester, 1889.)

AS we are informed in the preface, the volume before us is the first complete work treating of the vertebrate fauna of the two counties mentioned in the title, which has hitherto appeared, although scattered notes and a few lists have been published by several writers. The author, who, from his position as Curator of the Town Museum at Leicester, has exceptional opportunities for a work of this nature, can certainly claim that the result of his labours does not err on the side of incompleteness. Thus this volume is not only a record of all the existing species of vertebrates which have been observed within the limits of the counties in question, but likewise includes the fossil forms hitherto described from the same area. The recent and extinct forms are, indeed, arranged together in a systematic manner, without any difference of type or other indication to distinguish at a glance the fauna of the present from that of the past; and it is certainly rather startling, at first sight, to find in a fauna of an English Midland county the dormouse immediately followed by elephants and rhinoceroses. Now, although we are not on the side of those who regard the sciences of zoology and palæontology as separated by a wide gulf, yet we venture to think that in this instance the author would have been better advised had he given his synopsis of extinct types in a separate portion of the volume, after having first dealt with the existing species. Faunas are, indeed, to a very large extent, features of one particular epoch; and when we have those of two or more distinct epochs mixed up together, we tend to lose sight of the peculiar features of each one. The ordinary student of the local distribution of existing English mammals will find that the introduction of a number of extinct types, of which he knows nothing, tends to distract his attention from the observations regarding the local distribution of the living forms. Fortunately, indeed, this objection does not apply to the birds, in which no extinct forms are recorded.

The very natural tendency on the part of the author to make as much as possible of his subject, probably accounts for the introduction of some groups or species which might have been better omitted, or, at all events, passed over with a brief foot-note. Thus, in the first place, the introduction of the family *Hominidæ* could have been very well spared, at all events in the systematic arrangement. Then, again, the devoting of nearly two pages to the order Cetacea seems to be very unnecessary, seeing that the only ground for the introduction of this order into the fauna of Leicestershire is that the bones of whales are sometimes used as gate-posts, or in one instance as an ornament to a carriage-drive! The author's remark in the latter instance that he records "these, lest, in the event of their getting loose and being subsequently dug up, they should be mistaken for bones of an extinct elephant," reads as though intended for a caustic sarcasm against palæontologists. As another instance, we may mention the case of the avocet (p. 150), introduced on the ground that a gentleman fishing at the junction of the Soar with the Trent, at the extreme northern limit of West Leicestershire, saw what he believed to be an example of this bird flying overhead. The inclusion of species on this account would almost justify passengers passing through a town by railway being entered among the list of visitors thereto.

The same natural tendency to make the most of the subject will probably account for the introduction of sub-ordinal and sectional names (*e.g.* Carnivora Vera, Æluroidea, Arctoidea, &c.) which are of no possible importance in a work of this nature, and are really an incumbrance.

The author tells us he has followed the latest descriptions throughout his work, and we see that in several instances he is even in advance of many writers in regard to the adoption of early names on the ground of priority. Thus the name *Microtus* is employed for the voles, in lieu of the well-known *Arvicola;* but in this particular

instance it would surely have been well for the author to have departed from his rule and introduced the latter term as a synonym. A still more glaring instance of the inadvisability of dropping all mention of synonyms occurs in treating of the lesser shrew (p. 13), for which the name *Sorex minutus*, Linn., is adopted, in place of the later *S. pygmæus*, Pall. Now, the author refers to Bell's "British Quadrupeds" for the distinctive characters of this species, which is there mentioned only as *S. pygmæus;* thus laying himself open to the criticism of those who are not specialists that he has confused the terms *pygmæus* and *minutus.* This species has, moreover, never been recognized in the district, so that its mention seems rather unnecessary. In discarding the name *Lepus timidus* in favour of *L. europæus* for the common hare, our author follows those who regard the letter of the law as more than the spirit; and although there is but little, if any, doubt that at least some of the hares to which Linnæus applied the name of *L. timidus* were really of that species to which we commonly apply the name *L. variabilis*, yet we cannot help thinking that the former name might be advantageously retained in its common acceptation.

Among the Ungulata, the author retains the fossil *Bos longifrons* (*frontosus*) as a distinct species, although it has been shown over and over again that it can only be regarded as a race of *B. taurus.* Similarly, all recent observations tend to show that *Bos primigenius* is nothing more than a larger variety of the same species; while there appear to be no valid grounds for specifically distinguishing the Pleistocene *Bison priscus* from the living Lithuanian aurochs. The author would confer a great benefit upon palæontologists if he could show how the skull he refers to the so-called *Sus palustris* can be specifically distinguished from one of *S. scrofa.*

In commenting upon the absence of remains of fossil Carnivora from the Leicestershire Pleistocene, Mr. Browne does not appear to be aware how extremely rare these remains are in the equivalent deposits of other counties. Thus, at Barrington, in Cambridgeshire, where bones and teeth of Ungulates are found by the hundred, or thousand, those of Carnivores may be reckoned by units or tens; and the introduction of special hypotheses to account for their absence in Leicestershire is, therefore, quite superfluous.

The total number of mammals mentioned is forty-eight (including man), but of this list only twenty-five are now found in a wild state in the area described. The number of species of birds is very large, as we might expect in an area of the size of that forming the subject of the work. Several species, such as the gannet, cormorant, &c., are, however, but occasional stragglers from the coast; while in other cases, as we have already remarked, the evidence of occurrence within the two counties is of the slightest. A good lithographic plate of Pallas's sand-grouse, and a coloured one of the cream-coloured courser, are given; and we also have an elaborate table of the dates of arrival of summer immigrants. In the reptiles, the five existing species are almost lost among a number of fossil forms, to which they have but a very remote kinship. This swamping of recent forms by their fossil allies is, however, not so marked among the fishes, owing to the circumstance that all the fossil forms belong to extinct families, which follow the recent ones. Mr. Browne follows Prof. Cope in abolishing the orders Teleostei and Ganoidei, and arranging the representatives of the former and the typical groups of the latter in a sub-class Teleostomi, which is ranked as equivalent to the Elasmobranchii. The *Salmonidæ* are thus immediately followed by a family which the author, in defiance of all grammatical rules, terms *Leptolepidæ*, and which forms a transition from the Ganoids to the Teleostei. It seems strange that, while employing the correctly-formed term *Rhizodontidæ* (instead of *Rhizodidæ*), the author should retain names like *Leptolepidæ* and *Osteolepidæ* in place of *Leptolepididæ* and *Osteolepididæ*; but here, perhaps, he merely follows those who ought to know better. The number of fossil fishes from the Lias quarries of Barrow-on-Soar is very considerable; and we believe that the Leicester Museum is rich in this respect, as well as in the remains of Saurians from the same locality.

The author seems to have spared no labour in looking up references and making his work in all respects as nearly complete as possible; and, since the volume is handsomely got up and well printed, with a remarkable freedom from misprints, it should take a place in the first rank of local faunas. R. L.

THE SCIENTIFIC PAPERS OF ASA GRAY.

Scientific Papers of Asa Gray. Selected by Charles Sprague Sargent. Two Vols. (London: Macmillan and Co., 1889.)

NO more fitting monument could have been raised to the memory of the late Dr. Asa Gray—who was almost as well known to botanists on this side of the Atlantic as on the other—than a reprint of a selection o his numerous writings. During a period of upwards of fifty years he was actively engaged in the investigation and publication of the botany of North America, and studies of a wider range. As Prof. Sargent says, in his preface to the present collection, "The number of his contributions to science and their variety is remarkable, and astonishes his associates even, familiar as they were with his intellectual activity, his various attainments, and that surprising industry which neither assured position, the weariness of advancing years, nor the hopelessness of the task he had imposed upon himself, ever diminished."

The hopeless task, it may be explained, was a complete "Synoptical Flora of North America." Botanists need not be told how he laboured to complete this gigantic undertaking, even at an age when most men are past work. Taking up the work where the unfinished "Flora of North America," by Torrey and Gray, ceased thirty-five years previously, Gray published the remainder of the Gamopetalæ in 1878. This was followed in 1884 by a re-elaboration of the Compositæ and neighbouring natural orders; and the whole was re-issued in the form of one volume in 1886. This volume comprises about 1000 closely printed pages of descriptive matter—descriptive matter perhaps unsurpassed in botanical literature, and dealing with 567 genera and 3521 species. Whatever may be done by Gray's successors towards completing the "Synoptical Flora," his own contribution is a

most valuable one—valuable because it embodies the whole of his numerous scattered writings on the group in question.

In making a selection of Dr. Gray's work for republication, Prof. Sargent naturally did not choose descriptive botany, though an index to the genera and species described in a variety of more or less inaccessible publications would be of the utmost service to botanists; for even under the most favourable conditions a long time must elapse before the completion of the "Synoptical Flora."

The selection, "which was found difficult and embarrassing," is limited to reviews of works on botany and related subjects, essays, and biographical sketches, and it is on the whole, doubtless, as good a one as could have been made. Gray wrote "more than eleven hundred bibliographical notices and longer reviews," and, as space for only fifty is found in a volume of 400 pages, it follows that "it was necessary to exclude a number of papers of nearly as great interest and value as those which are chosen."

Dr. Gray's method, if I may so term it, of reviewing the productions of his contemporaries was of such an instructive, temperate, and impartially critical character that these reviews have a permanent value. On reading some of them again, one is more than ever impressed with the fact that he made himself thoroughly acquainted with the works he criticized, and that he well fulfilled his duty alike to the public and the author. He did not hesitate to point out what he regarded as defects in the writings of his most intimate friends; but he was more careful to give an analysis of the contents of a book, with his own views thereon, than to condemn it on its faults or weak points.

These reviews cover a wide field, as well as a long period, and still remain profitable and interesting reading. The selection is too limited to be a history of botany during the last half-century, but it is sufficiently comprehensive to give an idea of the most notable events. It is true that the essays on the Darwinian theory are not here reproduced, as they had already been republished by their author.

The first volume, which is devoted to reviews, commences with a detailed notice of the second edition of Lindley's "Natural System of Botany" and ends with Ball's "Flora of the Peruvian Andes," reminding us of our most recent loss in the very small circle of private gentlemen who may be said to have studied botany successfully.

Early among the reviews is that of Endlicher's "Genera Plantarum," a work published at intervals between 1836 and 1840; and, almost at the end, a short article on the completion of Bentham and Hooker's "Genera Plantarum," 1862–83. In the latter we find a comparison of the number of genera admitted in various works of the same class, from the appearance of the first edition of Linnæus's "Genera Plantarum," in 1737, down to Bentham and Hooker, and remarks on the ideas of generic limits entertained by the different authors, and on the relative quality of their work.

Interspersed between these are notices of such widely different subjects as De Candolle's "Prodromus"; von Mohl's "Vegetable Cell"; Boussingault, "On the Influence of Nitrogen"; Bentham's "Hand-book of the British Flora"; De Candolle's "Géographie Botanique"; Hooker's "Distribution of Arctic Plants"; Ruskin's "Proserpina"; Darwin's "Insectivorous Plants"; and Wallace's "Epping Forest."

Among the fourteen "Essays" in the second volume, those on the longevity of trees, the flora of Japan, Sequoia, and forest geography and archæology, may be named as specially interesting.

The biographical sketches are thirty-eight in number, ranging from Brown and Humboldt to Bentham and Boissier. As only some two hundred pages are devoted to them, these sketches are, many of them, necessarily very brief; but, as Gray had a personal knowledge of most of the men of whom he wrote, they contain original and interesting observations and facts not to be found elsewhere. And all who knew Dr. Gray will enjoy reading again his opinion of other men and their works.

W. BOTTING HEMSLEY.

MANURES AND THEIR USES.

Manures and their Uses. By Dr. A. B. Griffiths. (London: George Bell and Sons, 1889.)

THIS is a hand-book for farmers and students, and may be described as a smaller and less ambitious successor to the treatise on manures, by the same author, reviewed some months ago in NATURE. The principal value of this latter work consists in the direct information it contains as to sources of phosphatic, potassic, and nitrogenous manures, including guanos, in all parts of the world. The analyses, localities, amounts imported, and values, are all interesting facts for farmers, and this little book may well take its place in an agricultural library as supplying knowledge which otherwise might need research through many scattered sources of information. When, however, we consider the book as a means for imparting sound views on agricultural principles, we must advise caution on the part of the reader. Dr. Griffiths is one of those teachers who are infected with an inordinate affection for chemical manures. He believes, with M. Ville, that "the farmer who uses nothing but farmyard manure exhausts his land." Now, a man who starts with such an obvious fallacy can scarcely get into the right path. This doctrine is contrary to science and practice; and until Dr. Griffiths relinquishes it he cannot hope to enjoy the confidence of any farmer. We venture to put the matter in two or three positions from which it can be clearly viewed. Dr. Griffiths says, "This [farmyard] manure is erroneously supposed to contain *all* the necessary plant-foods required for the growth of crops." Erroneously! why, farmyard manure at least must contain all the constituents of straw, for it is largely made of straw. Similarly, it must contain the elements of turnips and root crops, when it is composed of them in no small proportion. Also it must contain the constituents of corn, because all meals and cakes which are consumed by cattle, and all hay, which is also consumed by cattle, contain the constituents of corn in the form of nitrogen, phosphorus, sulphur, potash, lime, magnesia, &c. Whether looked at chemically or approached through pure reasoning, it is clear that farm-

yard manure is the true restorer of fertility, the very milk of plants, the very life-blood of the soil, if such an expression may be allowed. Farmyard manure during its decay has its elements liberated from organic combinations gradually, and when wanted, as well as in a condition so available for the food of plants, that as a manure it is inimitable. No other manure can in all cases be applied to all crops with the same marked effects. It is strange that farmyard manure alone acts promptly and certainly upon leguminous crops such as beans, peas, and clover. No chemical manure, whether nitrogenous or phosphatic, can be relied upon to affect these crops, and yet farmyard dung tells upon them at once. Dr. Griffiths lays stress upon the fact that animals retain phosphates and nitrogen for the formation of bones, nerves, and muscles, and therefore to some extent rob the land. This fact is, however, entirely over-ridden by the customary importation of extraneous matter on to the farm in the form of foods purchased. The amount of phosphates and nitrogen removed by animals in their bodies is as nothing compared to the tons of cake, meal, hay, and even roots which are imported. Neither must we forget the town manure which is so often bought by farmers, and which will compensate for such a loss as that which Dr. Griffiths fears. Too much prominence is given to chemical manures, and too little importance is attached to stock-feeding as a manurial agency. Dr. Griffiths quotes many writers upon matters on which they are scarcely to be regarded as authorities. On such matters he might just as well have told us his opinion, instead of backing it up with the name of a solicitor who has been dead for years and whom nobody now knows of. Neither is an agriculturist, pure and simple, an authority on a chemical point such as the valuation of farmyard manure on the basis of its chemical constituent parts.

Dr. Griffiths claims to have made a discovery with regard to the use of iron sulphate as a fertilizer, and a good deal of space is devoted to this subject, which is not without interest. Half a hundredweight of iron sulphate per acre produces extraordinary results, according to experiments recorded in this book. No doubt this is Dr. Griffiths's great point, and far be it from us to detract from its significance. If it is as potent a fertilizer as Dr. Griffiths thinks, we shall probably hear more of it. He is evidently not the man to let the matter rest. W.

OUR BOOK SHELF.

Histoire Naturelle des Cétacés des Mers d'Europe. By P. J. Van Beneden. Pp. 664. (Brussels: F. Hayez. 1889.)

IT is fifty-three years since the veteran Professor of Zoology in the University of Louvain published his first paper on the Cetacea, entitled "Caractères spécifiques des grands Cétacés tirés de la conformation de l'oreile osseuse." During the greater part of this long period he has made this group of animals especially his own, having industriously collected from every available source information upon them, which he has given to the world, not only in his great works on the osteology of the Cetacea and the fossil Cetacea of Antwerp, but also in a series of memoirs which have appeared from time to time in the publications of the Belgian Academy of Sciences. During the last three years the "Mémoires couronnés et autres Mémoires," published by that learned body in octavo form, have contained a number of articles from his pen upon the Cetacea of the European seas, and it has been a happy idea of the author to collect these together, and republish them in a handy form, so as to render them accessible to many who would have difficulty in referring to them when scattered throughout the pages of the journal in which they first appeared.

The work treats systematically of all the species known to inhabit any of the seas by which Europe is surrounded, and under each species are sections devoted to the literature, the history, the synonymy, the characters, the organization, the habits, the geographical distribution, the mode of capture, the museums in which specimens are known to exist, the published figures, and finally an account of the commensals and parasites which dwell upon or within them. On all these subjects the information given is derived from years of close and diligent gathering, and the result is an exhaustive account of our present knowledge of the European Cetacea. As a book of reference to all who are engaged in the study of cetology this work is absolutely invaluable, and if figures, even in outline, of all the species had been added, it might have gone far to occupy the place of the much-needed popular hand-book of this still little understood, though interesting order of mammals.

The number of species admitted is judiciously restricted, many of those appearing in previous works being relegated either definitely or provisionally to synonyms. Twenty-six are, however, left, all undoubtedly distinct forms. Of these, seven are whalebone whales, viz. *Balæna biscayensis*, *B. mysticetus*, *Megaptera boöps*, *Balænoptera rostrata*, *B. borealis*, *B. musculus*, and *B. sibbaldii*; five are Ziphioids, viz. *Physeter macrocephalus*, *Hyperoödon rostratus*, *Ziphius cavirostris*, *Micropterus sowerbyi*, and *Dioplodon europæus*; and the remaining fourteen are Delphinoids, viz. *Phocæna communis*, *Orca gladiator*, *Pseudorca crassidens*, *Globicephalus melas*, *Grampus griseus*, *Lagenorhynchus albirostris*, *L. acutus*, *Eudelphinus delphis*, *Tursiops tursio*, *Prodelphinus tethyos*, *P. dubius*, *Steno rostratus*, *Delphinopterus leucas*, and *Monodon monoceros*. The only exceptions we can take to this nomenclature are the adoption of the generic term *Micropterus* in preference to *Mesoplodon*, as the former was preoccupied by a genus of Coleoptera, and the use of the needless term *Eudelphinus* for the common dolphin. If this should be generally accepted, the good old Linnean genus *Delphinus* would disappear altogether from the list. That it should be greatly restricted by the lopping off of aberrant branches was inevitable, but surely the name might have been left for such a characteristic species.

W. H. F.

Hand-book of Practical Botany for the Botanical Laboratory and Private Student. By E. Strasburger. Edited, from the German, by W. Hillhouse, M.A., F.L.S. Second Edition, Revised and Enlarged. With 116 original and 33 additional Illustrations. (London: Swan Sonnenschein and Co., 1889.)

THE first edition of Prof. Hillhouse's translation of Strasburger's "Practical Botany" was reviewed in NATURE (vol. xxxv. p. 556). The new edition has been considerably enlarged, and is now intermediate in extent between the smaller and the larger German editions. The new matter, mainly derived from the larger "Botanisches Practicum," second edition, adds greatly to the value of the book. The most important additions are the accounts of the reproduction of Fucus and of Chara, and of the fertilization and embryology of Picea. The much fuller description of the reproduction of Mucor must also be noticed, as well as the considerable alterations, affecting both text and figures, in the chapters on vascular bundles. Further, the structure of the grain of wheat is now described—a very useful addition.

Some verbal inaccuracies which had crept into the first translation have been corrected, and in every respect the editor may be congratulated on the work in its present form. It will be of the greatest use to students—especially, perhaps, to those who have to work alone.

D. H. S.

Traité d'Optique. Par M. E. Mascart. Tome I. (Paris: Gauthier-Villars, 1889.)

THIS is the first half of a very elaborate treatise on optics, the full scope of which we cannot tell till the second volume appears, as no hint is given of what is yet to come. This first volume begins with the fundamental principles of the wave-theory of light, deduces from them the elementary laws of geometrical optics, discusses the properties of a co-axal system of refracting surfaces, describes the structure of the eye, expounds the facts of colour-mixture, points out the conditions which determine the resolving power of a telescope, develops at great length the theories of diffraction and interference, with some of their principal applications, and devotes about 80 pages to polarization and double refraction. There is practically nothing about the microscope, and nothing at all about the paths of rays in media of continuously varying density.

The book is by no means easy reading, and the labour of perusing it is increased by the smallness of the reference letters (with their numerous accents and suffixes) which occur in the figures. The plan involves much specialization. For instance, the proof of the formula for retardation on which the theory of Newton's rings depends is not given in the sections devoted to Newton's rings and colours of thin plates, but some 370 pages earlier. In many cases, when the student has found a formula which appears to contain the information of which he is in quest, he has to search carefully through a long series of preceding pages before he can find the meaning of some symbol which occurs in it. The volume contains a vast store of information, but not generally in a form to suit hasty seekers after truth. It requires to be studied at leisure, and the time so spent will not be wasted. Great pains have obviously been taken to embody the latest information and present it in the clearest form. We may instance the spiral curves which illustrate the values of Fresnel's integrals, and the curve (to which a folding-plate is devoted) showing the relations of the colours of diffraction fringes to the three primary colours. There is an excellent discussion of the theory of concave gratings, both for reflection and refraction. The least attractive chapter is that entitled "Properties of Vibrations." It is a discussion of the composition of simple harmonic motions, and occupies 40 pages bristling with elaborate formulæ. We think a more moderate display of mathematics under this head would have sufficed.

The order of arrangement adopted in the volume is rather peculiar, and baffles all *a priori* conjecture. For instance, the discussion on colour-mixtures occurs in a chapter on "Interferences," and the investigation of the conditions which determine the resolving power of a telescope is given in the introductory chapter under the head of "Preliminaries."

The book is essentially a mathematical treatise, all experimental descriptions being reduced to the narrowest possible limits.

The preface states that the work is addressed mainly to "pupils of the Faculties and Schools of higher instruction," but we think its principal use in this country will be as a book of reference for teachers. Its value for this purpose will be greatly increased if a good alphabetical index is added at the end of the second volume.

J. D. EVERETT.

Bibliothèque photographique: Le Cylindrographe, Appareil panoramique. Par P. Moëssard, Commandant du Génie breveté, attaché au Service géographique de l'Armée. (Paris: Gauthier-Villars, 1889.)

THIS is a description of a photographic camera invented by Colonel Moëssard, in which the lens is pivoted on an axis, and the sensitive film is arranged in a cylindrical form about this axis, on a radius equal to the focal length of the lens. By this means a panoramic view of angular breadth up to 170° can be taken. The camera being fixed in position, the lens is uncapped, and then rotated quickly or slowly, according to the speed of the plate, and the intensity of light in any direction. The author claims for the instrument useful employment in surveying, either in the carefully detailed plans of an ordnance survey, or in the rapid views useful for warlike purposes, which the instrument can afford. Two photographs taken with the aid of the instrument illustrate very favourably its powers, especially for architectural purposes.

A Hand-book of Modern Explosives. By M. Eissler. (London: Crosby Lockwood and Son, 1889.)

IN this book the author of "Modern High Explosives" has collected much useful information about the various explosives now in use. The greater part of the work is devoted to nitro-compounds, but short accounts of the other types of explosives now being manufactured are added. The manufactures of gun-cotton and nitroglycerine receive full treatment, together with the modifications introduced in the various large factories both of America and Europe. The important subject of the use of explosives in fiery mines has a chapter to itself. The description of the tests of flameless powders is of especial interest; in fact, the official reports of the tests of many of the most important explosives are perhaps the most instructive portions of the book. The chapter dealing with the practical application of explosives should be useful not only to the miner, but also to officers of both services to whom blasting and the use of explosives generally may at any time become a necessary auxiliary. An interesting account of the history and trials of the Lalinsky gun, together with the manufacture and use of gun-cotton shells, is also well worthy of their perusal. Little is said on the use of explosives below water, especially on the subject of the removal of wrecks, which would stand far fuller treatment. Four appendices are added, two dealing with the analysis and determination of stability of explosives, and one containing abstracts from the principal provisions of the Explosive Act of 1875. Although there is much that is necessarily old, still this is a book that will be read with interest by most who are accustomed to work with high explosives. The illustrations are well executed, and the whole wonderfully free from printer's errors.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Peltier Effect, and Contact E.M.F.

WITHOUT any further reference to the heading of a letter on p. 102, signed "The Reviewer," I wish to discuss an interesting argument therein propounded as proving that a true electromotive force at contact between two metals cannot be the cause or sole cause of the Peltier effect, unless the latter be simply proportional to absolute temperature. The argument is very like one that I indistinctly remember to have heard suggested some time ago by Prof. Schuster, and it struck me at the time as ingenious and not easily answerable.

On seeing it in print, however, a natural answer occurs to me, which it may be worth while to give. The whole point of the reasoning depends on assumed properties of vacuum.

The assumptions are as follow :—

(1) That a perfect vacuum is an absolute non-conductor of electricity.

(2) That no contact E.M.F. exists between a metal and a vacuum.

(3) That vacuum has a specific inductive capacity.

Grant all these, and the argument is sound. Decline to admit any of them, and it proves nothing. Break down the first two of them, and it proves too much: it proves the non-existence of any thermal contact-force whatever between conductors. For if there were any E.M.F. at the metallic contact, and none at the other or vacuum contacts, a continuous current would flow, propelled by energy derived from a cold place.

This argument is indeed the ordinary one to prove that the algebraic sum of the E.M.F.'s at all the junctions of a closed conducting circuit in which no energy but heat is supplied must be zero when the temperature is uniform.

The proof scarcely holds when insulators are interposed, though the *fact* may be true nevertheless. When chemically active substances with their extraneous supply of energy are interposed, the fact itself is no longer true. But how do we know what is true when vacuum is interposed? The hypothesis on which the argument is founded is a baseless conjecture.

But it may be said, Are not the hypotheses probable? Do you not yourself believe them? I believe in (1) and (3) provisionally, but certainly not in (2). The contact E.M.F. between two substances is probably some surface action or skin phenomenon, and I see no reason why it should not occur as well in the boundary between metal and void as in the boundary between one metal and another. Indeed, it is not improbable that the sum of the E.M.F.'s in *every* circuit of chemically inert substances, whether conducting or not, and inclusive of vacuum, is zero under uniform temperature conditions.

All that is wanted to establish this is the knowledge that in a circuit of any one substance at non-uniform temperature the total E.M.F. shall be zero,[1] or that the Thomson effects in a single substance always balance each other; *i.e.* that the total E.M.F. in a circuit shall depend on a potential function of temperature, or $dE = f'(t)dt$.

Now it is quite true that this $f'(t)$ is the Peltier coefficient divided by absolute temperature, and that $f(t)$ in its most general form contains an arbitrary constant, but what of that? Nothing is known of $f(t)$ except that it is a potential function: it is not known to represent any physical effect. I never said that the Peltier effect enabled us to find the most general form of the function $f(t)$; I said it gave us the E.M.F. at a junction.

And there is much ground for the assertion; for it is easy to show that in a simple AB circuit, with junctions at t_1 and t_2, the total E.M.F. is

$$E = \Pi_1 - \Pi_2 + \int_{t_2}^{t_1}(\Theta_A - \Theta_B)dt;$$

just as if the resultant E.M.F. were the algebraic sum of two Peltier E.M.F.'s and of two Thomson E.M.F.'s.

My only contention is that this equation, which is undeniably true when the Π are interpreted as heat-coefficients, is also true and immediately interpretable when they stand for contact E.M.F.'s. The burden of proof as to the physical existence of an unnecessary and in every sense arbitrary constant rests with those who doubt this simple explanation.

It is difficult to see how a doubt can arise, or how the Peltier and Thomson productions or destructions of heat can be accounted for without local E.M.F.'s. Nohow, so Dr. Hopkinson has proved, and I also have insisted (*Phil. Mag.*, October 1885, and March 1886), except by some wildly gratuitous assumption of an actual physical specific heat for electricity, dependent on the temperature and on the metal in which it happens to be.

Liverpool, December 14, 1889. OLIVER J. LODGE.

[1] Hopkinson virtually pointed this out, *Phil. Mag.*, October 1885.

Mirages.

THE article in NATURE of November 21, 1889 (p. 69), recalls to me mirages I saw in March 1888, while travelling in the East on the steam yacht *Ceylon*.

On the 29th we were crossing the Black Sea from Sebastopol. It was a fine cool day and quite calm. In the afternoon a false or mirage horizon about 3° above the true one was visible for a few hours. No objects were within range of vision. The mirage disappeared as the sun declined.

The next day was very much warmer, and we saw a more marked and interesting mirage in the afternoon as we were steaming across the Sea of Marmora away from Constantinople. In this case it appeared only in the west, and objects were seen reflected in an inverted position. A small conical-shaped island was seen with its inverted image at times distinct from and at times blending with the original. The image was distinctly seen of some land, which was actually below the horizon. The mirage of the reflection of the sun in the sea was, when seen through a glass, especially beautiful. It resembled a glorious cataract of golden water. This mirage lasted till quite the dusk of the evening, and then gradually thinned down and died away.

I do not know whether mirages at sea are uncommon; but as the officers on board did not remember seeing one before, I thought these instances might be worth recording.

ARTHUR E. BROWN.

Thought Cot, Brentwood, December 31, 1889.

Self-luminous Clouds.

I AM very sorry that I took no notes, some six or seven years ago, on the first and only occasion of my seeing self-luminous clouds, but though I can give neither date nor positions, the following facts are still fresh in my memory.

Passing through Bushey Park after dark, I noticed an aurora borealis, and, as I had only recently seen the rather rare phenomena of the rays of the setting sun converging towards a point in the east, I followed the direction of one of the principal beams of light towards the south, when, at a point somewhat south of my zenith, I noticed an equatorial belt of luminous clouds. I found that each cloud belonged to a ray, and faded and brightened with it, but was separated by about 60° of clear sky. This belt of clouds extended down to the western horizon, the eastern one was obstructed by trees, while shortly afterwards small dark clouds appeared on that side, and the sky soon became overcast.

The luminous clouds were quite transparent, so that even faint stars could be seen through them when at their brightest. I have heard from Scandinavian captains that these luminous belts are sometimes seen in northern latitudes, and are sure signs of bad weather. I have written these few remarks in the hope that those of your readers who may have the chance of seeing an aurora borealis will also look out for these clouds, and if possible determine their position. C. E. STROMEYER.

Strawberry Hill, January 4.

The Revised Terminology in Cryptogamic Botany.

THE anglicized forms of most of the terms in common use, employed in the "Hand-book of Cryptogamic Botany" recently issued by Mr. G. Murray and myself, have not up to the present time found much support from our fellow-botanists. I propose, therefore, to give, in some detail, the reasons which have induced us to adopt them, and to urge their general use on writers on cryptogamic botany. For this purpose we will take as our text extracts from three reviews of the "Hand-book," marked, as all the critiques have been, with only one or two exceptions, by a generous appreciation of the difficulties of our task, and a too great leniency to the many shortcomings of the work:—"The most conspicuous, though not the most important, of these [changes] is the adoption of anglicized terminations for Latin and Greek technical words. This is a matter in which it is hard to draw the line aright. . . . As a matter of taste we think the authors have gone much too far in this direction. They complain of the 'awkwardness and uncouth form of these words'; we should have thought the reproach applied much more strongly to 'cœnobe,' 'sclerote,' 'nemathece,' and 'columel'" (NATURE). "An Englishman may guess what 'archegone' is short for, for example; but why puzzle a foreigner with a new form of a word with which he is familiar in every treatise hitherto written on the special subject in any European language?" (*Academy*). "Too sanguine expectations on this head might well be toned down by remembering the complete failure of the somewhat similar experiment made by Lindley. . . . Primworts, spurgeworts, bean-capers, and hip-

purids are decidedly simpler, even if less euphonious, than Primulaceæ, Euphorbiaceæ, Zygophyllaceæ, and Halorageæ; yet the longer Latin terms are still universally used, while the quasi-English ones have never obtained even temporary acceptance" (*Journal of Botany*).

The last of these criticisms appears to rest on a confusion between the principles of nomenclature and those of terminology. In nomenclature, rigid rules have been laid down, and accepted by all leading naturalists of all countries, in order that the scientific names of species, genera, orders, &c., may correspond in scientific treatises in all languages. In the terminology of flowering plants no such rule has ever been attempted to be laid down; but each writer, when writing in his own language, uses terms, usually of classical origin, and derived from common roots, but of a form as far as possible amenable to the laws of the language in which he writes. All that we are contending for is the extension of the same principle to cryptogamic botany; one of the main objects in the publication of our "Hand-book" being to make the study of flowerless plants as attractive to the public at large as is that of flowering plants.

In order to show how recent is the universal adoption of this practice in phanerogamic botany—a change largely due to the influence of Dr. Lindley's writings—we append a list of a few terms in use in standard works of original research or of reference, published within the last thirty-two years, which presented themselves the first to our hand; viz.—"The Miscellaneous Botanical Works of Robert Brown" (1866); Mr. Currey's translation of "Hofmeister on the Higher Cryptogamia, &c." (1872); Berkeley's "Introduction to Cryptogamic Botany" (1857); and Bentley's "Manual of Botany" (2nd ed., 1870):—

Achænium	Bentley	*Ovulum*	Brown
Anthera	Brown	*Perianthium*	Brown
Arillus	Bentley	*Pericarpium*	Brown
Bractea	Brown	*Pistillum*	Brown
Carpellum	Brown	*Rhizoma*	Berkeley
Integumentum	Berkeley	*Spermatozoon*	Currey
Involucrum	Brown	*Stamina* (plural)	Brown
Ovarium	Brown	*Stipula*	Currey

With the exception of words which have been incorporated into our language, such as *corolla*, *nucleus*, &c., comparatively few of those used in describing flowering plants now retain their classical forms; the most conspicuous exceptions being those applied to the structure of tissues, such as *epidermis* and those ending in *enchyma*; and can anything be more puzzling than the forms in common use for the terms derived from the Greek δέρμα—*epidermis*, *hypoderma*, and *periderm*? We have no doubt that, had our critic lived in the days of Robert Brown and Lindley, he would have thought all the innovations introduced by the latter "uncouth" simply because we were not used to them; and would have said that Lindley had "gone much too far." In some of those adopted by ourselves we have, in fact, been forestalled by others, as in the cases of *antherid* and *archegone* by Lindley, and *sporange* by Oliver.

We now come to the charge made by our critic in the *Academy*, that the terms we have introduced would "puzzle foreigners." Unfortunately, our polyglottism, or rather oligoglottism, will not allow us to vie with our reviewer in his acquaintance with every European language; we are compelled to confine ourselves chiefly to three; but these include by far the greater part of European botanical literature—in fact, every treatise which nine out of ten English readers will wish to consult in the original. The statement quoted above seems to have been rashly made.

In *Italian*, as far as our knowledge goes, the practice is absolutely uniform: no botanical writer of repute uses the classical forms; but every technical term has its Italian spelling and termination. To such an extent is this adaptation to the laws of orthography of the language carried, that we find "xylem" converted into *xilema*, "phloem" into *floema*, "hormogonium" into *ormogonio*, and "hyphæ" into *ife*; and this by the first writers "on special subjects."

Our acquaintance with *Swedish*, *Danish*, *Dutch*, and *Spanish* is too slight to allow us to speak with confidence; but in all these the general practice is, we believe, the same as in Italian, though not to the same extent; with the best writers, when writing in their own language, the use of terms with Latin or Greek terminations appears to be the exception rather than the rule.

In *French*, the practice is by no means so uniform as in Italian; but still that of the highest authorities is, on the whole, very decidedly in favour of French, rather than Latin or Greek, forms of the words in most common use. From works picked up almost at random, we select the following:—

Anthéridie	Van Tieghem, Guignard, Philibert, De Wildeman, Bornet, Thuret.	*Parenchyme*	Guignard, Heckel, Fayod, Bornet, Tulasne.
Archégone	Van Tieghem.	*Perithèce*	Costantin.
Baside	Tulasne, Roumeguère (*basidie*, Fayod).	*Pollinide* (Florideæ)	Guignard.
Capitule	Bornet.	*Procarpe*	Bornet, Thuret.
Conidie	Costantin, Roumeguère (*conid*, Bornet).	*Propagule*	Bornet.
Épiderme	Van Tieghem, Rénault.	*Prothalle*	Guignard.
Favelle	Bornet, Thuret.	*Pycnide*	Costantin, Roumeguère.
Gamétange	De Wildeman.	*Sclérote*	Van Tieghem, Fayod.
Gloméruie	Bornet, Tulasne.	*Sore*	Thuret.
Gonidie	De Wildeman.	*Sporange*	Bornet, Thuret, Roumeguère, Tulasne, Van Tieghem, De Wildeman, Guignard, Philibert.
Hormogonie	Bornet.	*Stipe*	Fayod, Roumeguère.
Hyphe	De Wildeman.	*Stomate*	Philibert, Thuret.
Nucléole	Guignard.	*Thalle*	Thuret, Gay, De Wildeman, Fayod.
Oogone	De Wildeman (*oogonie*, Roumeguère).	*Zoosporange*	Flahault.
Opercule	Philibert.		
Ostiole	Thuret, De Wildeman.		
Paraphyse	De Wildeman.		

The great stronghold of the conservatives in terminology is the *German* language. No doubt a large number of the best writers do here maintain the classical form of most technical cryptogamic terms, including some in which it has already been abandoned with us, such as *conceptaculum*, *receptaculum*, *stolo*, and *perianthium*, just as we still meet with *ovarium*, *ovulum*, and *protoplasma*. This is no doubt largely due to the greater difficulty which the German language has than the French or our own in naturalizing aliens. But even here the practice is by no means uniform, and Germanized forms are coming yearly more and more into use. In order that there may be no question as to the recency and authority of the examples quoted, the following list has been compiled exclusively from the standard treatises in Schenk's "Handbuch der Botanik"; had other works of equal authority been consulted, the list might have been considerably extended:—

Apophyse	Goebel	*Hormogon*	Zopf
Archespor	Goebel	*Mycel*	Zimmermann
Basidie	Zopf	*Paraphyse*	Zopf
Carpogon	Falkenberg	*Parenchym*	Haberlandt, Zimmermann, Detmer, Schenk, Zopf
Cilie	Zopf	*Plasmod*	Zopf
Collenchym	Haberlandt, Zimmermann	*Prokarp*	Falkenberg
Conidie	Zopf	*Sklerenchym*	Haberlandt, Detmer, Schenk
Endospor	Goebel	*Sporogon*	Goebel
Enzyme	Zopf		
Epithel	Haberlandt		
Exospor	Goebel		

We do not mean that these words are exclusively used by the writers quoted; it is not uncommon to find the Latin and the German form used indifferently on the same page. It is noteworthy also that even the most rigid conservatives do not use the Latin form in the plural of such words as "oogonium," "sporangium," "antheridium," "sclerotium," &c., but always the German forms, *Oogonien*, *Sporangien*, *Antheridien*, *Sklerotien*, &c.; such words as "oogonia," "sporangia," "antheridia," "sclerotia," &c., are, as far as our experience goes, to be found only in English and American writings and in Latin diagnoses.

Analyzing, therefore, the statement that the Latin and Greek forms of words used in cryptogamic terminology are "familiar in every treatise hitherto written on the special subject in any European language," we find that in Italian the practice is unanimously, and in French (as also, we believe, in most other European languages) preponderatingly in the opposite direction; and that German is the only widely read language of Continental Europe in which even the weight of authority is still on that side.

There are some terms in which, no doubt, the classical form must be retained, especially those which, when deprived of their

classical termination, become monosyllabic, such as "thallus," "sorus," "hypha," and "ascus," just as we still speak of a "corolla," a "stigma," a "hilum," and a "raphe." But, with regard to the great majority of terms in current use in descriptive cryptogamic botany, we entertain not the smallest doubt that the change will gradually be brought about which has, within the last forty years, become established in phanerogamic botany; and we would venture to suggest to our fellow-workers in cryptogamic botany in this country and in America, whether it will not be best to accept it frankly once for all.

ALFRED W. BENNETT.

Exact Thermometry.

I AM quite in agreement with Prof. Sydney Young (NATURE, December 19, p. 152), that after the lapse of a sufficient time—let us say, an infinite time—the constant slow rise of the zero-point of a thermometer at the ordinary temperature will attain a definite limit; but I cannot accept his view that the effect of heating the thermometer to a high temperature is simply to increase the rate at which *this* final state is approached. If the results of experiment at the ordinary temperature be expressed in a mathematical formula which admits of making the time infinite, the limiting value of the rise (on that condition) will not exceed on the average 2° C., even in a thermometer of lead glass. After exposure to a high temperature, and in the same thermometer, so great an ascent as 18° C. is a possible measurement, actually realized. The two phenomena are therefore very different in their nature.

The view that, owing to the more rapid cooling of the outer parts of the bulb after it has been blown, the inner parts are in a state of tension, and that it is the gradual equalization of the tension throughout the glass that causes the contraction, has frequently been held, and will probably be for a long time the favourite hypothesis upon the subject. It breaks down, however, when we attempt to calculate what the amount of the contraction might be, on the supposition that it is well founded: only a very small portion of the contraction could be thus accounted for. I regret that I cannot now conveniently refer to Guillaume's interesting demonstration of this result.

Prof. Young has placed on record an experiment with three thermometers, which he heated to 280° C. The zero movement, however, only ranged from 1° to 1°·2,—small readings which might very possibly have been obtained, or not, on either of the thermometers at other times. It is consequently very difficult to draw any inference from this experiment. I may, however, mention that closed thermometers made of lead glass are very apt to show a rise of zero after heating to about 120° C. and upwards to some temperature in the neighbourhood of 270° C., and after that a descent of zero; the temperature of 280° C. would in that case be an unsatisfactory one for a test experiment, and the effect of plasticity might very possibly be masked. On the other hand, if the three thermometers were of hard glass, all the zero movements would in that case be greatly diminished, and the results would be in less bold relief.

I do not know any substance more curious or interesting in its properties than glass; and I should be glad if Prof. Young—into whose able hands the matter has fallen—could decisively test my suggestion that plasticity is the main cause of the zero ascent after 120° C. Probably it has little or nothing to do with the ascent at the ordinary temperature. It is, however, known that fine threads of glass are undoubtedly plastic at the ordinary temperature.

EDMUND J. MILLS.

Melrose, N.B., December 29, 1889.

THE PALÆONTOLOGICAL EVIDENCE FOR THE TRANSMISSION OF ACQUIRED CHARACTERS.[1]

MUCH of the evidence brought forward in France and Germany in support of the transmission of acquired characters, which has been so ably criticized in Weismann's recent essays, is of a very different order from that forming the main position of the so-called Neo-Lamarckians in America. It is true that most American zoologists, somewhat upon Semper's lines, have supported the theory of the direct action of environment, always assuming, however, the question of transmission. But Cope, the able if somewhat extreme advocate of these views, with Hyatt, Ryder, Brooks, Dall, and others, holding that the survival of the fittest is now amply demonstrated, submit that, in our present need of an explanation of the origin of the fittest, the principle of selection is inadequate, and have brought forward and discussed the evidence for the inherited modifications produced by reactions in the organism itself—in other words, the indirect action of environment. The supposed arguments from pathology and mutilations have not been considered at all: these would involve the immediate inheritance of characters impressed upon the organism and not springing from internal reactions, and thus differ both in the element of time and in their essential principle from the above. As the selection principle is allowed all that Darwin claimed for it in his later writings, this school stands for Lamarckism *plus*—not *versus*—Darwinism, as Lankester has recently put it. There is naturally a diversity of opinion as to how far each of these principles is operative, not that they conflict.

The following views are adopted from those held by Cope and others, so far as they conform to my own observations and apply to the class of variations which come within the range of palæontological evidence. In the life of the individual, adaptation is increased by local and general metatrophic changes, of necessity correlated, which take place most rapidly in the regions of least perfect adaptation, since here the reactions are greatest; the main trend of variation is determined by the slow transmission, not of the full increase of adaptation, but of the disposition to adaptive atrophy or hypertrophy at certain points; the variations thus transmitted are accumulated by the selection of the individuals in which they are most marked and by the extinction of inadaptive varieties or species: selection is thus of the *ensemble* of new and modified characters. Finally, there is sufficient palæontological and morphological evidence that acquired characters, in the above limited sense, are transmitted.

In the present state of discussion, everything turns upon the last proposition. While we freely admit that transmission has been generally assumed, a mass of direct evidence for this assumption has nevertheless been accumulating, chiefly in the field of palæontology. This has evidently not reached Prof. Weismann, for no one could show a fairer controversial spirit, when he states repeatedly: "Not a single fact hitherto brought forward can be accepted as proof of the assumption." It is, of course, possible for a number of writers to fall together into a false line of reasoning from certain facts; it must, however, be pointed out that we are now deciding between two alternatives only, viz. pure selection, and selection *plus* transmission.

The distinctive feature of our rich palæontological evidence is that it covers the entire pedigree of variations: we are present not only at but before birth, so to speak. Among many examples, I shall select here only a single illustration from the mammalian series—the evolution of the molar teeth associated with the peculiar evolution of the feet in the horses. The feet, starting with plantigrade bear-like forms, present a continuous series of readjustments of the twenty-six original elements to digitigradism which furnish proof sufficient to the Lamarckian. But, as selectionists would explain this complex development and reduction by panmixia and the selection of favourable fortuitous correlations of elements already present, the teeth render us more direct service in this discussion, since they furnish not only the most intricate correlations and readjustments, but the complete history of the addition

[1] This article is an informal reply to the position taken by Prof. Weismann in his essays upon heredity. I have borrowed freely from the materials of Cope, Ryder, and others, without thinking it necessary to give acknowledgment in each case.

of a number of entirely new elements—*the rise of useful structures from their minute embryonic, apparently useless, condition*, the most vulnerable point in the pure selection theory. Here are opportunities we have never enjoyed before in the study of the variation problem.

The first undoubted ancestor of the horse is *Hyracotherium*; let us look back into the early history of its multicuspid upper molars, every step of which is now known. Upon the probability that mammalian teeth were developed from the reptilian type, Cope predicted in 1871 that the first accessory cusps would be found on the anterior and posterior slopes of a single cone, *i.e.* at the points of interference of an isognathous series in closing the jaws. Much later I showed that precisely this condition is filled in the unique molars of the Upper Triassic *Dromotherium*. These with the main cusp form the three elements of the tritubercular crown. Passing by several well-known stages, we reach one in which the heel of the lower molars intersects, and, by wearing, produces depressions in the transverse ridges of the upper molars. At these points are developed the intermediate tubercles which play so important a *rôle* in the history of the Ungulate molars. So, without a doubt, every one of the five main component cusps superadded to the original cones, is first prophesied by a point of extreme wear, replaced by a minute tubercle, and grows into a cusp. The most worn teeth, *i.e.* the first true molars, are those in which these processes take place most rapidly. We compare hundreds of specimens of related species; everywhere we find the same variations at the same stages, differing only in size, never in position. We extend the comparison to a widely separate phylum, and find the same pattern in a similar process of evolution. Excepting in two or three side lines the teeth of all the Mammalia have passed through closely parallel early stages of evolution, enabling us to formulate a law: *The new main elements of the crown make their appearance at the first points of contact and chief points of wear of the teeth in preceding periods.* Whatever may be true of spontaneous variations in other parts of the organism, these new cusps arise in the perfectly definite lines of growth. Now, upon the hypothesis that the modifications induced in the organism by use and disuse have no directive influence upon variations, all these instances of sequence must be considered coincidences. If there is no causal relationship, what other meaning can this sequence have? Even if useful new adjustments of elements already existing may arise independently of use, why should the origin of new elements conform to this law? Granting the possibility that the struggle for existence is so intense that a minute new cusp will be selected if it happens to arise at the right point, where are the non-selected new elements, the experimental failures of Nature? We do not find them. Palæontology has, indeed, nothing to say upon individual selection, but chapters upon unsuccessful species and genera. Here is a practical confirmation of many of the most forcible theoretical objections which have been urged against the selection theory.

Now, after observing these principles operating in the teeth, look at the question enlarged by the evolution of parallel species of the horse series in America and Europe, and add to the development of the teeth what is observed in progress in the feet. Here is the problem of correlation in a stronger form even than that presented by Spencer and Romanes. To vary the mode of statement, what must be assumed in the strict application of the selection theory? (*a*) that variations in the lower molars correlated with coincident variations of reversed patterns in the upper molars, these with metamorphoses in the premolars and pocketing of the incisor enamel; (*b*) all new elements and forms at first so minute as to be barely visible immediately selected and accumulated; (*c*) in the same individuals favourable variations in the proportions of the digits involving readjustments in the entire limbs and skeleton, all coincident with those in the teeth; (*d*) finally, all the above new variations, correlations and readjustments, not found in the hereditary germ-plasm of one period, but arising fortuitously by the union of different strains, observed to occur simultaneously and to be selected at the same rate in the species of the Rocky Mountains, the Thames Valley, and Switzerland! These assumptions, if anything, are understated. Any one of them seems to introduce the element of the inconstant, whereas in the marvellous parallelism, even to minute teeth markings and osteological characters, in all the widely distributed forms between *Hyracotherium* and *Equus*, the most striking feature is the constant. Viewed as a whole, this evolution is one of uniform and uninterrupted progression, taking place simultaneously in all the details of structure over great areas. So nearly does race adaptation seem to conform to the laws of progressive adaptation in the individual, that, endowing the teeth with the power of immediate reactive growth like that of the skeleton, we can conceive the transformation of a single individual from the Eocene five-toed bunodont into the modern horse.

The special application of the Lamarckian theory to the evolution of the teeth is not without its difficulties, some of which have been pointed out to me by Mr. E. B. Poulton. To the objection that the teeth are formed before piercing the gum, and the wear produces a loss of tissue, it may be replied that it is not the growth, but the reaction which produces it, which is supposed to be transmitted. Again, this is said to prove too much; why is the growth of these cusps not continuous? This may be met in several ways: first, in the organism itself these reactions are least in the best adapted structures, a proposition which is more readily demonstrated in the feet than in the teeth—moreover, since the resulting growth never exceeds the uses of the individual, there is a natural limit to its transmission; secondly, the growth of the molars is limited by the nutritive supply—we observe one tooth or part growing at the expense of another; third, in some phyla we do observe growth which appears to lead to inadaptation and is followed by extinction. In one instance we observe the recession of one cusp taking place *pari passu* with the development of the one opposed to it. These and many more general objections may be removed later, but they are of such force that, even granting our own premises, we cannot now claim to offer a perfectly satisfactory explanation of all the facts.

The evidence in this field for, is still much stronger than that against, this theory. To sum up, the new variations in the skeleton and teeth of the fossil series are observed to have a definite direction; in seeking an explanation of this direction, we observe that it universally conforms to the reactions produced in the individual by the laws of growth; we infer that these reactions are transmitted. If the individual is the mere pendent of a chain (Galton), or upshoot from the continuous root of ancestral plasm (Weismann), we are left at present with no explanation of this well-observed definite direction. But how can this transmission take place? If, from the evident necessity of a working theory of heredity, the *onus probandi* falls upon the Lamarckian—if it be demonstrated that this transmission does not take place—then we are driven to the necessity of postulating some as yet unknown factor in evolution to explain these purposive or directive laws in variation, for, in this field at least, the old view of the random introduction and selection of new characters must be abandoned, not only upon theoretical grounds, but upon actual observation.

Reading between the lines of Weismann's deeply interesting essays, it is evident that he himself is coming to this conclusion. HENRY FAIRFIELD OSBORN.

Princeton College, August 23.

A FIELD LAID DOWN TO PERMANENT GRASS.

A VALUABLE paper, by Sir J. B. Lawes, on the history of a field laid down to permanent grass, has been reprinted, by Messrs. Spottiswoode, from the Journal of the Royal Agricultural Society of England. The field in question forms part of the Rothamsted estate, and was laid down to permanent grass nearly thirty years ago, by Dr. Gilbert, to whom it was let in 1856. It has been mown for hay every year from the commencement; and in the present pamphlet Sir J. B. Lawes gives full particulars as to the economical results, the constituents supplied in the manures and removed in the crops, the changes within the soil in the formation of the meadow, and the botany of the meadow. The following are his summary and general conclusions:—

(1) By the judicious employment of manures, both natural and artificial, arable land has been converted into permanent grass, not only without loss, but with some profit to the tenant.

(2) The important constituents, nitrogen and phosphoric acid, were supplied in the manures in larger quantities than they were removed in the crops; but potash in only about the same quantity as it was removed.

(3) The application of dung, not only compensates for much of the exhaustion from the removal of hay, but it has a beneficial influence on the botanical character of the herbage.

(4) Although the grass has been mown every year for nearly thirty years, there has been a considerable accumulation of fertility within the soil.

(5) Analysis has shown that there has been an increase of nitrogen in the surface-soil, beyond that which could be explained by excess supplied in manure over that removed in crops, and by the combined nitrogen coming down in rain, and the minor deposits from the atmosphere. Part, if not the whole, of this increase is probably derived from the subsoil by deeply-rooted plants, which afterwards leave a nitrogenous residue within the surface-soil. Or, possibly, some of it may have its source in the free nitrogen of the atmosphere, brought into combination within the soil, under the influence of micro-organisms, or other low forms.

(6) In laying down arable land to permanent grass, especially if hay is to be removed, it is essential to supply, not only nitrogenous, but an abundance of mineral manures, and especially of potash, a large quantity of which is removed in the crops, and must be returned. When the grass is not mown, but fed, the exhaustion is much less, but it is greater when consumed for the production of milk than when for that of store or fattening increase.

THE TOTAL ECLIPSE OF DECEMBER 22.

MISFORTUNE has attended the double-expedition sent by the Royal Astronomical Society to observe the total eclipse of December 22. In Africa observations were made impossible by bad weather. Observations were secured off the coast of French Guiana, but at a cost which is deeply to be deplored—the death of Father Perry.

The telegram received from Demerara is as follows:—"104 corona American Perry dead dysentery." With regard to the part of this telegram which needs explanation, the *Times* of January 6 says:—"104 is resolvable into the factors 2, 4, and 13, of which the first number means that the weather was only moderately good; the second that successful exposures were made with the Abney 4-inch lens, but that the development was not carried out, owing either to unfavourable climatic conditions, or possibly to the illness of Father Perry; and the third, that successful photographs were obtained with the 20-inch mirror, but again the development was not completed. The words corona American signify most probably that the corona was of the same form as that seen on January 1, 1889, when a total eclipse was successfully observed in California, and the form was then that now generally ascribed to a period of minimum sun-spots, elongated at the sun's equator and radial but short at the poles."

NOTES.

THE list of those who received New Year's honours and appointments included Brigade-Surgeon George King, F.R.S., Bengal Medical Service, Superintendent of the Royal Botanical Gardens, Calcutta. He has been made Companion of the most eminent order of the Indian Empire.

THE seventy-second anniversary of the Institution of Civil Engineers occurred last Thursday, when a revised list of the members of all classes showed that the numbers on the books amounted to 5904, representing an increase of $3\frac{1}{3}$ per cent. in the past twelve months.

THE Institution of Electrical Engineers will hold the first meeting of the current term this evening, when the President, Dr. John Hopkinson, F.R.S., will deliver his inaugural address.

THE annual general meeting of the Royal Meteorological Society will be held at 25 Great George Street, Westminster, on Wednesday, the 15th inst., at 7.15 p.m., when the Report of the Council will be read, the election of Officers and Council for the ensuing year will take place, and the President (Dr. W. Marcet, F.R.S.) will deliver an address on "Atmospheric Dust," which will be illustrated by a number of lantern slides.

THE *Mining Journal* is to be congratulated on the very admirable portait of Dr. Archibald Geikie which appeared in its issue of December 28. The portrait was accompanied by a short but very good account of Dr. Geikie's life and labours.

DR. RAOUL GAUTIER has been appointed Professor of Astronomy at the University of Geneva, and has at the same time been made director of the Observatory. His father, Colonel E. Gautier, retains his connection with the latter establishment, with the title of honorary director.

THE Professorship of Agriculture and Rural Economy at the Royal Agricultural College, Cirencester, vacant by the resignation of Prof. McCracken, has been conferred upon an old student and gold-medallist of the College, Mr. James Muir.

THE arrangements of the Royal Botanic Society for 1890 include exhibitions of spring flowers on March 26 and April 23; summer exhibitions of plants, flowers, and fruit, on May 14 and June 11; and an evening *fête* and exhibition on July 2. Botanical lectures will be given on May 9, 16, 23, and 30, and on June 6 and 13. These lectures will be free to all visitors in the Gardens.

ON Thursday, January 16, Prof. R. Meldola, F.R.S., will begin a course of twelve special evening lectures at the Finsbury Technical College, on coal-tar products. The object of the course is to describe the technology of the raw materials manufactured from the tar. The theoretical treatment will serve as a general introduction to the chemistry of the aromatic compounds. A syllabus can be had on application to the College.

In May next, the six hundredth anniversary of the foundation of the University of Montpellier will be celebrated.

M. Cosson, member of the French Academy of Sciences, and the author of many memoirs on the flora of Algeria and Tunis, died a few days ago in Paris, and was buried on the 4th inst.

We review to-day the volumes which conclude the series of Reports on the zoological results of the *Challenger* Expedition. In a prefatory note introducing Vol. II. of the Report on Physics and Chemistry, just issued, Dr. Murray explains that with the exception of a volume on deep-sea deposits, which will be issued in March next, and a summary volume, which, it is hoped, may be finished in about a year thereafter, the entire series of Reports is now completed. These Reports have been issued at intervals during the last nine years, whenever ready, and without any reference to systematic arrangement. They are bound up in forty-seven large quarto volumes, containing 27,650 pages of letterpress, 2662 lithographic and chromo-lithographic plates, 413 maps, charts, and diagrams, together with a great many woodcuts.

Some time ago Mr. J. T. Cunningham, Naturalist at the Plymouth Marine Biological Laboratory, wrote to the *Times* about the occurrence of anchovies on the south coast of England. In another letter, printed in the *Times* on Wednesday, he has given some fresh information about the matter. From Mr. Whitehead, of Torquay, he learns that the sprat fishermen at that place were catching a number of anchovies in their sprat nets together with sprats; that about a fifth of their catches consisted of anchovies. Mr. Dunn has sent him specimens from Megavissey. These were caught, as it were, accidentally in pilchard nets. Mr. Cunningham has made inquiries among the pilchard and herring fishermen at Plymouth, and finds that almost every time they shoot their nets they catch a few anchovies—from one to a dozen. The mesh of a pilchard net is much too large to hold an anchovy, and these occasional specimens are caught only in parts of the nets that get entangled; they are not meshed in the ordinary way. Of the anchovies he has obtained from the pilchard fishermen, he says there is no doubt whatever as to their being of the same species (*Engraulis encrasicholus*) as those which we import from France and Italy.

A rather serious subsidence has occurred near Dane Bridge, Northwich. A large hole, nearly 10 feet deep and covering a space of 50 feet by 30 feet, has been formed near the roadway. The Bridge Inn is now 24 inches out of the perpendicular, or some 5 inches more than it was before the subsidence. The inn had been securely bolted and the walls secured some time since, otherwise it would probably have collapsed. Some wooden structures standing on the opposite side of the road have been rendered untenantable. The gas and water mains were dislocated, and had to be repaired by the local board.

The General Report of the Survey of India Department for 1887–88, which has recently been published, indicates a gradual increase in the annual amount of work done. The triangulation along the Madras Coast has been extended 370 miles in length; and similar operations have been conducted in Baluchistan, one series along a parallel of 30° N., and another along the meridian of 67° E., both meeting at Quetta and having an aggregate length of 270 miles. The topographical surveys during the year covered an area of 15,673 square miles. It is gratifying to note that the system, started in the previous year, of employing the village *patwáris* as cadastral surveyors has been continued with very encouraging results, the aggregate area surveyed cadastrally being 5435 square miles. The special telegraphic longitude operations were resumed, and 7 arcs of longitude in Southern India measured, with the particularly interesting result of indicating an excess of gravitation toward the ocean surrounding India. Geographical surveys in Burmah have been made on a large scale, the Ruby Mine tract receiving special attention. A valuable addition to our knowledge of Afghanistan is furnished by the report of Yusuf Sharif, who accompanied the Afghan Boundary Commission, and succeeded in surveying 4600 miles of new country on his return. The statistics of the output of maps and reproductions at the principal offices show a marked increase. The value of the Dehra Dun station for purposes of solar photography is forcibly demonstrated by the fact that photographs of the sun were obtained on no less than 327 days, and forwarded to the Solar Physics Committee, to complete the Greenwich series. The Report is accompanied by the usual maps and narratives of the various expeditions.

We owe a new and interesting application of photography to M. Bertillon, the well-known director of the Identification Department at the Paris Prefecture of Police. M. Bertillon has been devoting himself for some months to the study of the physical peculiarities engendered by the pursuit of different occupations. The police have frequently to deal with portions of bodies, and it would greatly aid their investigations to be able to determine the calling of the murdered person in each particular case. The hand is as a rule the part naturally most affected by the occupation, and M. Bertillon has taken a very large series of photographs, each one showing on a large scale the hands, on a smaller scale the whole figure of the workman at his work, so that one may see at a glance the position of the body, and which are the parts that undergo friction from the tools in use. From the hands of the navvy all the secondary lines disappear, and a peculiar callosity is developed where the spade handle rubs against the hand; the hands of tin-plate workers are covered with little crevasses produced by the acids employed; the hands of lace-makers are smooth, but they have blisters full of serum on the back and callosities on the front part of the shoulder, due to the friction of the straps of the loom; the thumb and the first joints of the index of metal-workers show very large blisters, whilst the left hand has scars made by the sharp fragments of metal. Experts in forensic medicine (Vernois among others) have before drawn attention to the subject, but this is the first time that an investigation has been carried out on a large scale, and in M. Bertillon's hands it should lead to the best results.

Shocks of earthquakes continue to be felt in the province of Semiryetchensk, Russian Turkestan. After September 12, they were felt nearly every day, the most severe shocks having been experienced on September 17, at 11.45 a.m.; on the 22nd, at 1.15 p.m.; on the 23rd, at 4.55 a.m. On September 30, at 6.30 p.m., there was a particularly severe shock, preceded by a loud underground noise.

Severe shocks of earthquake were felt on the northern and north-eastern shores of Lake Issyk-kul nearly every day from November 19 to December 5. Many chimney-pots in several villages were destroyed by the shock of November 19.

The latest information as to the earthquake which visited Lake Issyk-kul on July 12 is given in the *Akmolinsk Gazette*. It lasted from 3.15 to 3.30 a.m., and destroyed, or rendered uninhabitable, all buildings in the villages Uital, Sazanova, Preobrajensk, and Teplyi Klutch, of the Issyk-kul district. Eight persons were killed, and 43 injured, some of them severely. The greatest disasters, however, appear to have occurred among the Kirghizes, who camped in the Kunghei Alatau, on the northern shore of Lake Issyk-kul. They had no fewer than 26 killed and 15 injured. The numbers of cattle killed during the earthquake were: 283 horses, 75 horned cattle, and 379 sheep. Several villages of the district

of Vyernyi also suffered very much. At Przevalsk (formerly Karakol, on the southern shore) and the surrounding villages many houses were destroyed; while amidst the Taranchis of the district of Vyernyi 21 persons were killed and 2 severely injured. At Vyernyi itself (50 miles north of the lake) the earthquake was relatively feeble; but at Jarkend all houses were rendered uninhabitable. In the west of Lake Issyk-kul the shocks were feeble, but in the north the wave of the earthquake spread as far as Kopal (180 miles from Issyk-kul, as the crow flies), and even as far as Sergiopol, which is 380 miles distant from the northern shore of the lake.

THE Council of the Italian Meteorological Society, publishes an *Annuario Meteorologico*, in which will be found much useful information for general readers. The volume for 1890 contains 276 small octavo pages, and is divided into four parts:—(1) Ephemerides and astronomical tables. This part also contains a special appendix giving the concordance of the calendars and other particulars of the 17 eastern nations. (2) Tables for the reduction of meteorological observations, by Padre Denza, with useful examples of how the corrections are applied, and also meteorological and magnetical statistics. (3) Geographical and topographical elements, together with an instructive paper on recent electrical terms and measurements. (4) A series of short articles on various sciences, among which we may specially mention one by Padre Denza, on the mode of determining the meridian line and time, for the use of observers who have only simple instruments. The most recent ideas upon the formation of hail, by Prof. L. Bombicci. On the types of isobars which favour frosts, by Prof. P. Busin, with suggestions for any observers willing to work at this subject. And, on the cause of earthquakes, in which the various theories are discussed, by Dr. C. De Giorgi.

THE Deutsche Seewarte has published, in a separate memoir, the results of the meteorological observations taken at its nine coast stations for the two lustra 1876–80 and 1881–85, together with summaries for the whole decade. The work contains very useful information relating to the climate of Northern Germany, and the hope is expressed that other institutions will publish similar results for their respective systems. In *Symons's Monthly Meteorological Magazine* for November it is pointed out that the years begin with December, in opposition to the regulations of the Vienna Congress that the years should begin with January, and an explanation of this is asked for. The explanation is given in the introduction: by this method the Seewarte has been able to give seasonal means, as well as monthly means. The December observations, which precede those for January, are for the same year as all the other months, not for the preceding year. The greatest annual range of temperature is 107°·1 at Neufahrwasser. The greatest daily rainfall occurred at Hamburg—viz. 3·37 inches. The annual percentage of rainy days varies from 41·6 to 59·7.

THE Annual Report of the Chief Signal Officer of the United States, for the year 1889, sets forth the extended and important character of the meteorological work that is carried on. Apart from weather forecasts, and storm warnings, the duties include the gauging and reporting of rivers, the reporting of temperature and rainfall conditions for the cotton interests, frost warnings in the interest of agriculture, and the notification of advancing cold waves for the benefit of the general public. The Chief Signal Officer estimates that the gratuitous distribution of meteorological data in the United States in a single week is greater than in all Europe in the entire year. The weather forecasts are issued twice daily, at 8 a.m. and 8 p.m., for a period of twenty-four hours, and the percentage of success shows a general average of 81. The present system of flag signals gives clear and definite information as to whether a storm is to be light or severe, whether its centre is approaching or has passed the station, and from what quarter high winds are expected. With regard to scientific researches, systematic observations of atmospheric electricity have been made, to determine whether these could be made use of in weather forecasting, the result being that negative electricity may be observed without being in any way related to precipitation, past, present, or future, and that such observations do not promise to be of practical use. Prof. C. Abbe has prepared a popular and non-mathematical exposition of the laws of storms, with a view to their better prediction. The Chief Signal Officer states that the Report brings together many new results, and that Prof. Abbe finds the source and maintaining power of a storm in the absorption by the cloud of solar heat, and in the liberation of heat in the cloud by those particles that subsequently fall to the ground as rain or snow, and endeavours to show that the movement of the storm centre is principally influenced by the location and amount of such precipitation.

REMARKABLE electrical phenomena are witnessed at the new observatory on the steep and isolated Säntis (8215) in Northern Switzerland. Thunderstorms are extremely frequent; thus in June and July last year, only three days were without them. As a rule, thunder peals from midday till evening. The noise is short, partly owing to shortness of flashes and partly to the small amount of echo. The thunderstorms come on quite suddenly, in a clear sky. One of the surest indications of their approach is the bristling of the observer's hair. During hail, the iron rods of the house give a hissing sound, associated with luminous effects.

M. E. HOSPITALIER, the electrician, has begun the publication of a work in two volumes, entitled "Traité Elémentaire de l'Energie électrique." The first volume, comprising the definition, principles, and general laws, has been issued. Vol. II., on industrial applications, will be issued during the present year.

IN the current number of the *American Naturalist* Mr. Clement L. Webster gives an interesting account of various "mound-builder mounds" near Old Chickasaw, Iowa. Speaking of three human skeletons found in one of these mounds, the writer says that the crania show "an extremely low grade of mental development." They are smaller than the Neanderthal skull.

M. VAYSSIÈRE has published the second part of his monograph of the Opisthobranchiate Mollusca of the Gulf of Marseilles. It contains many fine plates.

THE origin of the very extensive pampas-formation in South America, a humus-covered loess of fine dust-like material, from 100 to 160 feet thick, with limestone concretions, and numerous fine passages, has attracted the attention of several geologists. From an important recent contribution to the subject by Roth (German Geological Society), it would appear that wind, river, lagoon, and coast deposits may all be distinguished in the pampas. The coast deposits are chiefly recognized by sand and marine shells. The lagoon formations are darker in colour and of small extent and thickness. The deposits from rivers are either from those rising in the mountains, or from those rising in the pampas themselves. The former contain, near the mountains, blocks of stone rolled down, and the granular nature of the deposit grows ever finer in the course of the rivers, which lose themselves in the pampas, in a region rich in lagoons, with a pretty abundant vegetation under recurrent rains. The deposits from the poor streams rising in the pampas have round, smooth, lime concretions, with smooth bone fragments of mammals. But most extensive are the æolic or air formations, of which the vertical root-like tubes and irregularly-formed lime concretions are characteristic. Violent winds carry the fine water-deposited

material in all directions over the plains till vegetation comes and retains it. The uniform character of the pampas loess arises, according to Roth, not from the material and mode of deposition, but chiefly from its transformation under the influence of vegetation. The roots taking up the matters they need, decompose the soil, and the humus arising from the decay of the plants acts on the new material spread over the surface by wind and rain, along with fresh plants, by way of decomposition. A further metamorphosis occurs by water carrying down matter through the porous layers, with the result of new combinations, and a harder, more compact loess in the lower parts. From observations of marine Tertiary beds of (probably) Miocene age in Entre Rios, over typical pampas loess, Roth infers that the formation of loess began some time in the Eocene period; in diluvial times it grew in intensity, and has gone on till now without interruption.

AN interesting study has been lately made by Herr Tarchenoff (*Pflüger's Archiv*) of electric currents in the skin from mental excitation. Unpolarizable clay-electrodes, connected with a delicate galvanometer, were applied to various parts—hands, fingers, feet, toes, nose, ear, and back; and, after compensation of any currents which occurred during rest, the effects of mental stimulation were noted. Light tickling with a brush causes, after a few seconds' period of latency, a gradually increasing strong deflection. Hot water has a like effect; cold, or the pain from a needle-prick, a less. Sound, light, taste, and smell stimuli act similarly. If the eyes have been closed some time, mere opening of them causes a considerable deflection from the skin of the hand. Different colours here acted unequally. It is remarkable that these skin-currents also arise when the sensations are merely imagined. One vividly imagines, *e.g.*, he is suffering intense heat, and a strong current occurs, which goes down when the idea of cold is substituted. Mental effort produces currents varying with its amount. Thus, multiplication of small figures gives hardly any current; that of large, a strong one. If a person is in tense expectation, the galvanometer mirror makes irregular oscillations. When the electrodes are on hand or arm, a voluntary movement, such as contraction of a toe or convergence of the eyes, gives a strong current. In all the experiments it appeared that, with equal nerve excitation, the strength of the skin-currents depended on the degree to which the part of the skin bearing the electrodes was furnished with sweat-glands. Thus some parts of the back, and upper leg and arm, having few of these, gave hardly any current. Herr Tarchenoff considers that the course of nearly every kind of nerve-activity is accompanied by increased action of the skin-glands. Every nerve-function, it is known, causes a rise of temperature, and accumulation of the products of exchange of material in the body. Increase of sweat-excretion favours cooling, and the getting rid of those products.

A METEORITE of special interest to chemists has been examined by M. Stanislas Meunier. It fell at Mighei, in Russia, on June 9, 1889, and it was evident, from a cursory inspection, that it was of a carbonaceous nature. In external appearance it exhibited a deep greenish-black colour, relieved by numerous small brilliant white crystals; the surface was considerably wrinkled, and blown out into swellings. The material was very friable, and readily soiled the fingers. A section under the microscope was observed to consist largely of opaque matter interspersed with crystals of a magnesian pyroxene and peridote. Fine particles of metallic iron and nickeliferous iron were readily collected by a magnet from the powdered rock, having all the characteristics of meteoric iron. The density of the meteorite was not very high, 2·495. About 85 per cent. of the rock was found to be attacked by acids, the portion so attacked being shown by analysis to consist mainly of a silicate of magnesium and iron having the composition of peridote. On the remaining 15 per cent. being heated in a current of dry oxygen gas, it readily took fire and burnt brilliantly. The products of combustion, which were allowed to pass through the usual absorption tubes containing pumice and sulphuric acid and potash, showed that the meteorite contained nearly 5 per cent of organic matter. In order to obtain some idea as to the nature of the carbonaceous substance present, a quantity of the rock was powdered and then digested with alcohol; on evaporation the alcoholic extract yielded a bright yellow resin, which was readily precipitated from the alcoholic solution by water, and much resembled the kabäite of Wöhler. The most curious chemical properties of the meteorite, however, are exhibited with a cold aqueous extract of the powdered rock. The filtered liquid is quite colourless, but exhales a faint odour due to an organic salt which carbonizes on evaporation to dryness, and may be burnt upon platinum foil. The aqueous extract further contains nearly 2 per cent. of mineral matter possessing properties of a novel character. Barium chloride solution gives a heavy white precipitate, which, however, is not barium sulphate. Silver nitrate gives a voluminous curdy reddish-violet precipitate, reminding one of silver chromate, but of quite a distinct and peculiar tint, and which blackens in a very few minutes in daylight. The substance which exhibits these reactions is unchanged by evaporation to dryness and ignition to redness, readily dissolving in water again on cooling and giving the above reactions. The silver nitrate precipitate, when allowed to stand for some time undisturbed in the liquid, becomes converted into colourless but brilliantly refractive crystals, which polarize brightly between crossed Nicols under the microscope, and which are insoluble in boiling water. The properties of this new substance contained in the water extract appear to approximate most closely to those of certain metallic tellurates, but the new compound appears also to differ in certain respects from those terrestrial salts.

THE additions to the Zoological Society's Gardens during the past week include a Brown Capuchin (*Cebus fatuellus* ♂) from Guiana, presented by J. H. Bostock; a Common Gull (*Larus canus*), a Black-headed Gull (*Larus ridibundus*), British, presented by Mr. E. Keilich; two Schlegel's Doves (*Chalcopelia puella*) from West Africa, presented by Major C. M. MacDonald; a Common Barn Owl (*Strix flammea*), British, presented by Mr. H. Craig; two Swainson's Lorikeets (*Trichoglossus novæ-hollandiæ*) from Australia, deposited.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m., January 9 = 5h. 17m. 32s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) Nebula in Orion ...	—	Greenish.	5 29 52	− 5 29
(2) 20 Leporis U.A. ...	6	Reddish-yellow.	5 6 14	−11 59
(3) η Orionis	4	Whitish-yellow.	5 19 0	− 2 30
(4) β Tauri	2	White.	5 19 18	+28 31
(5) 99 Birm.	8	Reddish-yellow.	5 4 25	− 5 38
(6) U Canis Minoris ...	Var.	Reddish?	7 35 22	+ 8 38
(7) T Arietis	Var.	Yellow.	2 42 11	+17 3

Remarks.

(1) The bright lines so far recorded in the visible part of the spectrum of the Great Nebula in Orion are as follows:—

Wave-lengths.		Observers.
5872 (D_3)	...	Dr. Copeland.
559·	...	Mr. Taylor.
520	...	"
500	...	Dr. Huggins.
495	...	"
486 (F)	...	"
470	...	Mr. Taylor.
447	...	Dr. Copeland.
434 (G)	...	Dr. Huggins.

The principal line in the photographic spectrum is near wave-length 373, and this seems to be special to certain parts of the nebula, according to Dr. Huggins's researches.

Although so much admirable work has already been done, there is still abundant scope for further investigations. One of the chief points requiring attention at present is the character of the brightest line, near λ 500. Researches on the spectra of meteorites, coupled with previous records of the line as having a fringe on its more refrangible side, led Prof. Lockyer to suggest, in 1887, that it was the remnant of the fluting near λ 500 seen in the spectrum of burning magnesium. Observations have since been made by Prof. Lockyer, Mr. Taylor, and myself, and all agree that the line is not sharp on the more refrangible side. Further observations are suggested. High dispersion is not necessary, or indeed desirable.

Direct comparisons of the chief nebula line with the magnesium fluting are also required, but this is an observation of great delicacy, requiring high dispersion. It must also be demonstrated that under the same conditions of comparison the F line of hydrogen is coincident with the third nebula line.

It has been suggested that the line near 559 recorded by Mr. Taylor is the remnant of the brightest manganese fluting; this can only be decided by direct comparisons.

In my own observations I noted that the F line is not seen in all parts of the nebula, and in this respect it resembles the ultra-violet line. This localization of the lines opens up a new field of work.

(2) This is one of the finest examples of stars of Group II. The bands 1 to 9 are perfectly well seen, but there is no record of the presence or absence of line absorptions. Observations of the carbon flutings are suggested, a spirit-lamp flame being convenient for comparisons. The two flutings to be examined, both for position and compound structure, are those near λ 517 and 474. The latter is a group of five flutings, extending from about λ 468 to λ 474, and under some conditions the point of maximum brightness of the group is shifted from 474 to 468. Comparisons of bands 4 and 5 with the brightest flutings of manganese and lead should also be made.

(3) This is a star with a spectrum of the solar type, of which the usual differential observations are required. The relative thicknesses of the hydrogen and other lines should also be noted.

(4) Gothard describes this star as belonging to Group IV. The usual observations are required.

(5) This is a star of Group VI., in which band 9 is dark, and band 6 pale. Dunér does not record any of the secondary bands. These and absorption lines should be looked for.

(6) This variable has a period of 423 days, and ranges from 8·5 at maximum to 13·5 at minimum (Gore). The spectrum has not yet been recorded. Maximum on January 9.

(7) This is a variable with a spectrum of the Group II. type. The period is 324 days, and the magnitude varies from about 8 at maximum to 9·5 at minimum. The maximum will not occur until January 17, but observations for the bright lines of hydrogen, &c., may be commenced at once. Variations of the widths and intensities of the bands before and after maximum may also be looked for.

A. FOWLER.

IDENTITY OF COMET VICO (1844) WITH BROOKS'S (1889).—In a note on some comets of short period (*Bulletin Astronomique*, November 1889), M. L. Schulhof observes that a comparison of the elements of Vico's comet (1844) given by Le Verrier with those of Brooks's comet (1889) shows a striking similarity. According to Mr. Chandler (*Astronomical Journal*, No. 205), Brooks's comet in May 1886 was at a distance 0·064 from Jupiter, and in heliocentric longitude 185°, whilst Vico's comet found itself about 1885-86, according to the elements of M. Brünnow in heliocentric longitude 162°, and approximately 0·4 from Jupiter. M. Schulhof adds, however, that the only objection to the hypothesis is that the action of Jupiter at a distance 0·4 would hardly have been sufficient to change so considerably the perihelion distance and the time of revolution. It will be sufficient to calculate back the perturbations of Brooks's comet as far as 1885 to definitely settle this question.

An investigation of the elements of Comets Lexell and Finlay has led to the conclusion that they are not identical, but the results found are not to be taken as conclusive, a farther and more exact determination of the elements of Finlay's comet having been undertaken.

OBSERVATIONS OF SOME SUSPECTED VARIABLES.—Observations of Lalande 26980 = 14h. 42·7m. + 6° 28′·9 (1875), by Rev. John G. Hagen, of Georgetown College, give the negative result that there is no proof of variation between the years 1884-89, and although an average of 15 observations a year have been made, the extreme range of magnitude is less than 0·2.

Three stars were found that showed rather a large difference from the Bonn D.M. magnitudes, and were watched from 1886 to 1889. No variation, however, was noticed during these three years. The following are the three stars and the magnitudes found compared with Argelander's :—

		m. m.	m.
D.M. 55·2587	...	7·8 ± 0·1;	D.M. = 8·8.
D.M. 44·3368	...	7·6 ± 0·1;	D.M. = 7·0.
D.M. 44·3402	...	7·7 ± 0·0;	D.M. = 8·1.

SPECTRUM OF A METALLIC PROMINENCE.—Prof. Vogel in a letter to Prof. Tacchini (*Mem. Società Spettroscopisti Italiani*, November 1889) observes that the positions of the lines measured in a metallic prominence on June 28 were incorrectly given by Prof. Spoerer in the *Memorie* for October (see NATURE, vol. xli. p. 115), and that the following should be substituted :—

Wave-length.	Origin.	Wave-length.	Origin.
667·6	Fe	553·4	Ba, Fe, Sr.
C	H.	531·6	Ceronium.
649·6	Ba.	526·9	Ca, Fe.
646·2	Ca.	518·8	Ca, Fe.
D_1	Na.	b_1	Mg.
D_2	Na.	b_2	Mg.
D_3	Helium.	b_3	Fe, Ni.
		b_4	Mg, Fe.

The above table only contains a small number of the bright lines seen in this eruption.

COMET SWIFT (*f* 1889, NOVEMBER 17).—The following corrected elements are given by Dr. Zelbr (*Astr. Nachr.*, 2944) :—

T = 1889 November 29·66411 Berlin Mean Time.

$$\left.\begin{array}{rcl} x &=& 40^\circ\ 55'\ 52''{\cdot}8 \\ \Omega &=& 331\ \ 26\ \ 40{\cdot}1 \\ \iota &=& 19\ \ \ 3\ \ 21{\cdot}1 \end{array}\right\}\text{Mean Eq. 1889·0.}$$

$$\phi = 39\ \ 8\ \ 23{\cdot}1$$

$$\log a = 0{\cdot}559784$$

$$\log \mu = 2''{\cdot}710331$$

Period = 6·91 years.

Dr. Lamp has computed the ephemeris given below from these elements :—

1890.	R.A. h. m. s.	Decl. ° ′	1890.	R.A. h. m. s.	Decl. ° ′
Jan. 8	1 19 48	+25 50·9	Jan. 19	1 59 43	+27 46·2
9	23 25	26 2·8	20	2 3 21	27 55·0
10	27 2	26 14·4	21	6 59	28 3·5
11	30 39	26 25·7	22	10 36	28 11·8
12	34 17	26 36·7	23	14 14	28 19·8
13	37 54	26 47·5	24	17 51	28 27·4
14	41 32	26 58·0	25	21 28	28 34·8
15	45 10	27 8·2	26	25 4	28 41·9
16	48 48	27 18·1	27	28 40	28 48·7
17	52 27	27 27·7	28	2 32 15	28 55·3
18	1 56 5	27 37·1			

The brightness on Jan. 8 = 0·48 and on Jan. 28 = 0·30, that at discovery being taken as unity.

M. Schulhof notes (*Bulletin Astronomique*, November 1889) that, according to the elements of this comet, it is probably identical with Blanpain's comet (1819), which M. Clausen has shown to be identical with Grischow's comet (1743).

SOLAR SPOTS AND PROMINENCES.—In the November *Memorie della Società degli Spettroscopisti Italiani*, Prof. Tacchini contributes a note on spots and faculæ observed from July to September of this year. A comparison of these observations with those of the preceding quarter shows an augmentation of the phenomena described and a diminution of the frequency of days without spots.

Spectroscopic observations made by Prof. Tacchini during the same period as the above show the mean daily number of prominences to have been 2·93, with an average altitude of

38″·8. This is an increase on the results of the preceding quarter both in the number and height of prominences. Two elaborate plates are included in the *Memorie*, indicating the prominences observed at Rome and Palermo from September to December 1886.

GEOGRAPHICAL NOTES.

THE following news was received a few days ago at St. Petersburg from Colonel Roborovski, the present chief of the late M. Prjevalsky's projected expedition. They crossed the Tian-Shan by the Barskaun and Bedel Passes, and reached the Taushkan-daria. Then they crossed the Kara-teke chain, and when they were on the banks of the Yarkend river, they found out that the Kashgar-daria no longer reaches the Yarkend-daria, but is lost in the irrigation canals of Maral-bash. They followed the Yarkend river, which rolls a mass of muddy water between quite flat banks, covered for some 15 to 30 miles on both sides of the river, by thickets of *Populus euphratica*, *Populus prunosa*, tamarisks, *Halostachus* shrubs, and rushes. Sand deserts spread on both sides,—towards the west to Kashgar, and eastwards to Lob-nor. Many ruins of old cities are met with in the deserts which are never visited by the natives. In the thickets of shrubs which fringe them there are numbers of tigers and wild boars, while amidst the *barkhans* of the deserts the wild camels are freely grazing. From Yarkend, the expedition went south, towards the hilly tracts, where it stayed for a month, and then it moved towards Kotan, whence Colonel Roborovski wrote on October 7. He proposed to winter at Niya, and to search for a pass to Tibet across the border-ridge to which Prjevalsky gave the name of "Russian Ridge." If they succeed they will spend next summer in Tibet.

IN a lecture lately delivered before the Geographical Society of Bremen, Prof. Kuekenthal, of Jena, gave some account of his researches in King Charles Land. Geologically, these islands belong to Spitzbergen, and not, as was formerly supposed, to Francis Joseph Land. During his stay of nearly three months, Prof. Kuekenthal thoroughly investigated this remote district, which is almost unapproachable, the surrounding seas being densely packed with icebergs. The islands are almost entirely without vegetation; only a few mosses struggle for existence on the clay soil. Numerous walrus skeletons are thrown up by the sea. Game is plentiful; Prof. Kuekenthal shot 14 bears (besides bringing back two live specimens), 39 walruses, and as many seals. Many insects and crustaceans were obtained from the land lakes.

THE ANNIVERSARY OF THE ROYAL SOCIETY.

THE President, after giving an account of the scientific work of many Fellows deceased during the past year, addressed the Society as follows:—

On account of the great importance of Joule's labours, both directly, in the advancement of science, and indirectly, through the knowledge thus acquired, in enabling improvements to be made in the practical application of science for industrial purposes, it has been suggested that it might be desirable to raise some public memorial to him, and the Council has appointed a Committee to consider the question.

I have referred, and that very briefly, to some only of the Fellows whom we have lost during the past year, but fuller details both of them, of other Fellows whom we have lost, and of our recently deceased Foreign Members, will be found in the obituary notices which appear from time to time in the Proceedings, according as they are received from the Fellows who have kindly undertaken to draw them up.

Of those who last year were on our list of Foreign Members, we have since lost one who was truly a veteran in science. More than three years have elapsed since the celebration of the centenary of the birth of M. Chevreul, and two more recurrences of his birthday came round before he was called away. He will be known for his researches on the contrast of colours. But his great work was that by which he cleared up the constitution of the fixed oils and fats, and established the theory of saponification. Few scientific men still surviving were even born when this important research was commenced—a research in the course of which he laid the foundation of the method now universally followed in the study of organic compounds, by showing that an ultimate analysis by itself alone is quite insufficient, and that it is necessary to study the substances obtained by the action of reagents on that primarily presented for investigation.

There is one whose name, though he was not a Fellow, I cannot pass by in silence on the present occasion. I refer to Thomas Jodrell Phillips Jodrell, who died early in September, in his eighty-second year. About the time of the publication of the reports of the Duke of Devonshire's Commission, the subject of the endowment of research was much talked of, and Mr. Jodrell placed the sum of £6000 in the hands of the Society for the purpose of making an experiment to see how far the progress of science might be promoted by enabling persons to engage in research who might not otherwise be in a condition to do so. But before any scheme for the purpose was matured, the Government Grant for the promotion of scientific research was started, under the administration of Lord John Russell, then Prime Minister. This rendered it superfluous to carry out Mr. Jodrell's original intention, but he still left the money in the hands of the Society, directing that, subject to any appropriation of the money that he might make, with the approval of the Royal Society, during his lifetime, the capital should, immediately upon his death, be incorporated with the Donation Fund, and that in the meantime the income thereof should be received by the Royal Society. Of the capital, £1000 was several years ago assigned to a fund for the reduction of the annual payments to be made by future Fellows, and the remaining £5000 has now, of course, been added to the Wollaston Donation Fund. By the Fee Reduction Fund the annual payment of ordinary Fellows elected subsequently to the time of the change was made £3 instead of £4, and the entrance fee abolished. As to the Donation Fund, a very wide discretion was, by the terms of the original foundation, left in the hands of the Council as to the way in which they should employ it in the interest of science.

Since the Croonian Foundation for lectures was put on its present footing, it has been made the means of securing for us the advantage of a lecture delivered before the Society by distinguished foreign men of science. In the present year our Foreign Member, M. Pasteur, was invited to deliver the lecture. Unfortunately, the state of his health would not allow him to deliver it himself, but at one time he hoped that he would have been able to be present at its delivery. It was ultimately arranged that his fellow-labourer at the Pasteur Institute, Dr. Roux, should deliver the Croonian Lecture in his stead; and several of the Fellows have heard his lucid account, first of the discoveries of M. Pasteur in relation to diseases brought about by microscopic organisms, and then further researches of his own in the same field.

In addressing the Fellows at the anniversary last year, I mentioned that Commandant Desforges had kindly offered to compare that portion of Sir George Schuckburgh's scale, with reference to which the length of the seconds pendulum had been determined by Kater and Sabine, with the French standard metre; and as the ratio of this to the English standard yard was accurately known, the length of the pendulum, as determined by these accurate observers, would thus for the first time be brought into relation with the English yard by direct comparison with accurately compared measures of length. The comparison was shortly afterwards executed, and the scale, which, of course, was very carefully packed for its journey to Paris and back, has long since been replaced in the apartments of the Society. This highly desirable comparison occupied but a few days in its execution; which affords one example of the scientific advantages derivable under an international agreement, from the establishment of the Bureau des Poids et Mesures. Our own country, which for some years held aloof from the Convention, forming the sole exception to the general agreement among nations of importance, joined it some years ago; and we thus have the privilege of availing ourselves, as occasion may arise, of the appliances at the office in Paris for such comparisons of measures of length or weight.

The services of Mr. Arthur Soper, as a special assistant, have been retained during the past session, with advantage to the library. He has completed the much-needed shelf catalogue, and the re-arrangement of the books where necessary. In the course of this work the volumes of a purely literary character

have been collected together, and a selection of the most valuable have been preserved in a properly protected case. Of the remainder, about 150 volumes (in addition to those reported last year) have been presented to various public libraries, and a slip catalogue of the volumes which are retained, containing about 1700 entries, has been prepared.

The manuscripts (other than the originals of ordinary papers read at the meetings) which have accrued to the Society since the publication of Halliwell's Catalogue have been collected from various parts of the building into the Archives Room, with the object of preparing a complete catalogue of the manuscripts at present in the possession of the Society.

Since the last anniversary, twenty-four memoirs have been published in the Philosophical Transactions, containing a total of 753 pages and 33 plates. Of the Proceedings, twelve numbers have been issued, containing 1062 pages and 6 plates. Dr. R. von Lendenfeld's "Monograph of the Horny Sponges," mentioned in my last anniversary address, has also been issued during the year in a quarto volume of 940 pages of text and 51 plates.

The Fellows are aware that for a great many years the Royal Society has devoted a part of its funds to the collection, preparation for the press, and correction of the proofs of a Catalogue of Scientific Papers. We have endeavoured to make the work as complete as possible, and to include scientific serials in all languages. The first part, covering the period 1800-63, is printed in six thick quarto volumes, of which the last appeared in 1872. The decade 1864-73 occupies two more volumes, of which the second was published in 1879. This work, in the preparation of which the Royal Society has spent a large sum, is for the benefit of the whole civilized world, and the sale of it could not be expected nearly to cover the cost of printing, paper, and binding. On a representation to this effect being made to Government, when the first part was ready for the press, the Lords of the Treasury consented that it should be printed at the public expense, the proceeds of the sale of the work, after reserving a certain number of copies for presentation, being repaid to the Treasury. In consideration of the large outlay involved in the preparation, those Fellows of the Society who wished to purchase the work could do so at about two-thirds of the cost to the general public. A similar application to the Treasury with reference to the decade 1864-73 met with a similar response, and we proceeded, as I mentioned at the anniversary last year, with the preparation of the manuscript for the next decade, 1874-83, which was then nearly ready. On making application towards the end of last year to the Treasury for the printing of this decade, our request was not acceded to. While declining, however, to continue any further the printing of this great work, the sum of £1000 was put in the Estimates, and has since been voted by Parliament, to assist us in the publication, and the copies of the work still remaining unsold have been handed over to us. This has enabled us to conclude negotiations with Messrs. Clay and the Syndics of the Cambridge University Press for the printing of the decade last mentioned, and at the same time to make some provision towards the future continuation of the work, without, as it may be hoped, encroaching to a greater extent than hitherto on our own resources.

The utility of the work would obviously be much increased if it could be furnished with some sort of key enabling persons to find what had been written on particular subjects. I am not without hopes that this very desirable object may yet be accomplished, notwithstanding the magnitude of any such undertaking.

Within the last year the Council of the Royal Society has accepted a duty in connection with scientific agriculture, of which it will be interesting to the Fellows to be informed. It is well known that for the last fifty years, or thereabouts, Sir John Lawes has carried out on his estate at Rothamsted an elaborate and most persevering series of experiments on the conditions which influence the growth and yield of crops of various kinds, the effect of manures of different kinds, the result of taking the same crop, year after year, from off the same land without supplying to it any manure, &c. Long as these experiments have already been continued, there are questions, particularly as regards the capabilities of the sub-soil, which require for their satisfactory answers that similar experiments should be continued on the same land for a still longer period. In respect of such questions, the investigator of the science of agriculture is in a position resembling that in which the astronomer is often placed, in having to make observations, the full interest of which it must be left to posterity to enjoy.

To prevent the interruption of these experiments, which it would take a life-time to repeat on fresh ground, and at the same time to provide for the carrying out of researches generally bearing on the science of agriculture, Sir John Lawes has created a trust, securing to the trustees a capital sum of £100,000, and leasing to them for ninety-nine years, at a peppercorn rent, certain lands in his demesne on which the experiments have hitherto been carried on, together with his laboratory. The trust is intended to be for original research, not for the instruction of students. The general direction of the experiments and researches to be carried on is vested in a committee of management consisting of nine persons, of whom four are to be appointed by the President and Council of the Royal Society.

The trustees named in the deed were Sir John Lubbock, Dr. Wells, and our Treasurer, Dr. Evans. One of these is now no more. Lord Walsingham has been appointed a trustee in place of the late Dr. Wells.

The Copley Medal for the year has been awarded to Dr. Salmon for his various papers on subjects of pure mathematics, and for the valuable mathematical treatises of which he is the author. Dr. Salmon's published papers are all valuable. Among others may be mentioned his researches on the classification of curves of double curvature, and on the condition for equal roots of an equation; the very important theorem of the constant anharmonic ratio of the four tangents of a cubic curve; his researches on the theory of reciprocal surfaces; his paper on quaternary cubics. But any notice of his contributions to the advancement of pure mathematics would be incomplete which did not specially mention his invaluable text-books on conic sections, higher plane curves, solid geometry, and the modern algebra—works which not only give a comprehensive view of the subjects to which they relate, but contain a great deal of original matter.

Of the Royal Medals, it is the usual though not invariable practice to award one for mathematics or physics, including chemistry, and one for some one or more of the biological sciences. No distinction is, however, made between the two medals in point of order of precedence, and I will, therefore, take the names of the medallists in alphabetical order.

The Council have awarded one of the Royal Medals this year to Dr. Walter Holbrook Gaskell for his researches in cardiac physiology, and his important discoveries in the anatomy and physiology of the sympathetic nervous system.

In his memoir, "On the Rhythm of the Heart of the Frog" (Croonian Lecture, Phil. Trans., 1882), and in a subsequent memoir, "On the Innervation of the Heart of the Tortoise" (*Journ. of Physiol.*, vol. iv.), Dr. Gaskell very largely advanced our knowledge of the physiology of the heart-beat, more especially as relates to the sequence of the beats of the several parts, the nature of the inhibitory action of the vagus nerve, and the relations of tonicity and conducting power to rhythmical contraction. These memoirs, however, lacked completeness on account of their not taking into full consideration the action of the cardiac augmentor or accelerator fibres, the existence of which had been previously indicated in the case of mammals, and suspected in the case of the frog and allied animals.

By a striking experiment (*Journ. of Physiol.*, vol. v.) Dr. Gaskell subsequently gave the first clear demonstration of the presence in the frog of cardiac augmentor fibres; also he gave a clear account of the nature of the action of their fibres, and the relations of that action to the action of the vagus fibres. Revising his previous work by the help of the light thus gained, Dr. Gaskell was enabled to give the first really consistent and satisfactory account of the nature of the heart-beat, of the modifications of beat due to extrinsic nerves, and of the parts played by muscular and nervous elements respectively.

Important as was this work on the heart, Dr. Gaskell's subsequent work "On the Structure, Functions, and Distribution of the Nerves which govern the Vascular and Visceral Systems" (*Journ. of Physiol.*," vol. vii.) has a far higher importance and significance. In spite of the knowledge which during the past thirty or forty years has been gained concerning vaso-motor nerves and the nerves governing the movements of the viscera, physiologists had up to the time of the appearance of Dr. Gaskell's memoir failed to obtain a clear conception of the nature and relations of the so-called sympathetic nervous system. By his researches, in which the several methods of

gross anatomical investigation, minute histological examination, and experimental inquiry were, in a striking manner, made to assist each other, Dr. Gaskell, by tracing out the course and determining the nature of vaso-constrictor and vaso-dilator fibres, and comparing them with the cardiac augmentor and inhibitory fibres, and with the fibres governing the visceral muscles, has already reduced to order what previously was to a large extent confusion, and has opened up what promises to be the way to a complete understanding of the whole subject.

The results arrived at, besides their great physiological importance, on the one hand promise to be of great assistance in practical medicine, and on the other are eminently suggestive from a purely morphological point of view.

The other Royal Medal has been awarded to Prof. Thomas Edward Thorpe for his researches on fluorine compounds, and his determination of the atomic weights of titanium and gold.

Prof. Thomas Edward Thorpe's experimental work has secured for him a place in the first rank of living experimentalists.

His researches, which are not confined to one department of chemical science, but extend over many branches, are all distinguished both by accuracy and originality of treatment. As examples of the high character of his investigations, those of the determinations of the atomic weights of titanium and gold may be specially cited as permanently settling the value of two most important chemical constants; whilst his researches on the fluorine compounds, including the discovery of thiophosphoryl fluoride, a body capable of existing undecomposed in the state of gas, and his latest work on the vapour-density of hydrofluoric acid, do not fall short of the highest examples of classical chemical investigation.

The Davy Medal has been awarded to Dr. W. H. Perkin for his researches on magnetic rotation in relation to chemical constitution.

Dr. Perkin is well known as the originator of what is now a great industry, that of the coal-tar colours, by his preparation and application to tinctorial purposes of a colouring matter which had previously merely been noticed as affording a chemical test for the presence of aniline. This, however, is now a long time ago, and it is for more recent work, the interest of which is purely scientific, that the medal has been awarded to him.

Dr. Perkin first showed, in 1884, that a definite relationship exists between the chemical constitution of substances and their power of rotating the plane of polarization of light when under magnetic influence; and he pointed out how the "molecular coefficient of magnetic rotation" or "molecular rotatory power" might be deduced.

In 1884 he presented to the Chemical Society a lengthy paper describing his method, and the results obtained for a very large number of paraffinoid hydrocarbons and haloid and oxygenated derivatives thereof; from these he deduced "constants," which he has since shown to be applicable in calculating the magnetic rotatory power of paraffinoid compounds generally. From time to time he has published further instalments of his work, and only quite recently has described the results obtained on examining nitrogen compounds, which exhibit many most interesting peculiarities.

The results are of special value on account of the exceptional care devoted to the preparation of pure substances, and the guarantee, which Dr. Perkin's reputation affords, that everything possible has been done to secure accuracy; and also because the substances chosen are for the most part typical substances, or belong to series in which a simple relationship exists.

HAIL-STORMS IN NORTHERN INDIA.

In a paper recently published in the Journal of the Asiatic Society of Bengal, Mr. S. A. Hill describes certain severe hail-storms and tornadoes that occurred on April 30 and May 1, 1888, in the Gangetic *doab* and Rohilkand in Northern India.[1] Tornadoes are not very common in India, but they appear to have been somewhat more prevalent than usual in the spring of 1888, the storms in question having been preceded on April 7 by a very destructive tornado at Dacca in Bengal, a full description of which was given by Mr. Pedler and Dr. Crombie in a previous number of the Society's Journal. Like all previously recorded storms of this character, these occurred in the spring, when the seat of minimum pressure is established in the Lower Punjab, and a trough of low pressure extends from this region eastward to the Gangetic plain. To the south of this trough very dry west winds, the hot winds of Northern India, prevailed in Rajputana and Central India, while, to the north of it, damp easterly winds blew up the northern margin of the plain and across the outer slopes of the Himalaya. It is apparently in the meeting of these two winds, where the former blows in an upper, the latter in the lower, stratum, that are generated the thunder squalls that form a normal feature of the spring months in Northern India; and tornadoes, as Prof. Ferrel has shown, are merely an exaggerated development of the thunder squall. In the present instance, ordinary storms of this character, and dust storms, occurred pretty generally over all the north-western districts of the North-West Provinces, simultaneously with the tornadoes in Rohilkand and the Gangetic *doab*.

[1] *Op. cit.*, vol. lviii., Part 2, No 2, 1889.

From the evidence quoted by Mr. Hill, it does not appear indeed to be positively established that any of the storms described exhibited all the characteristic features of tornadoes, as was undoubtedly the case of the Dacca storm. No mention is made in any of the reports of any whirling column having been actually observed; and that whirlwinds were the real agents of destruction seems to be inferred chiefly from the destructive force of the wind, especially its lifting power, and some rather vague reports on the wind's changes during the passage of the storm. On a point of this kind, however, in India, negative evidence goes for little, and the chief subject discussed in Mr. Hill's paper, viz. the conditions which determine these atmospheric disturbances, is of equal interest, whether they were really tornadoes or only remarkably severe hail-storms of the more usual kind.

In the barometric changes of the days preceding the storms there does not appear to be anything that throws much light on their genesis. The relative distribution of pressure shown by the observations on the Indo-Gangetic plain underwent but little variation, and the existence of a slight secondary depression in the immediate neighbourhood of the storm tract, on April 30, is inferred solely on the evidence of two Himalayan stations at elevations of 5300 feet and 6000 feet above the sea, and may be delusive. There had, however, been a general steady fall of the barometer for three days before the storms of April 30—one of those oscillations, apparently, which Mr. Abercromby has termed surges, and a rapid rise set in after the storms. As has been pointed out elsewhere, this is an ordinary recurrent feature of the season.

It is in the changes in the vertical distribution of temperature that Mr. Hill finds the conditions that determined the atmospheric disturbance. Taking as his fundamental data the observed temperatures of the three stations, Roorkee at 886 feet, Dehra at 2233 feet, and Mussooree at 6881 feet, and assuming that these represent approximately the rate of vertical decrease over the neighbouring plain, he computes the fall of temperature for increments of 1000 feet up to 10,000 feet by means of a simple formula of interpolation, and finds that, up to the forenoon of April 30, the condition of unstable equilibrium which results from the diurnal heating of the plains did not extend beyond 3000 or 4000 feet above the ground surface. This would set up a considerable amount of convective interchange between these lower strata, but the cloud-forming strata would still be in a stable condition, at least in a non-saturated atmosphere. On the afternoon of April 30, the conditions were changed. With a great fall of temperature at the lowest and highest stations, as compared with the previous day at the same hour, that of the intermediate station was but little affected, and hence the computed table shows a reduction of the vertical decrement at low levels, a corresponding increase at the higher levels, and a transfer of the condition of unstable equilibrium from the former to the latter. Simultaneously with this change took place that violent disturbance of the atmosphere that resulted in the hail-storms on the plains.

Mr. Hill's conclusions are entirely in accord with what might be expected on *a priori* grounds. But before they can be fully accepted, it is necessary to scrutinize the data, and as the result of this scrutiny we must confess they do not seem to us completely convincing. We may put aside the question whether and to what extent the empirical formula of interpolation adopted by Mr. Hill really expresses the law of decrement of temperature, since, although it would evidently fail for extrapolation much beyond the altitude of 7000 feet, it probably does not involve any very serious error below that limit, provided the numerical values afforded by observation are trustworthy. The

critical point of the whole reasoning is whether the observed temperatures at the three stations Roorkee, Dehra, and Mussooree, can be safely accepted as approximately representing those of the free atmosphere over the plains at the same levels, and this seems to us at least open to question. In the case of the lowest and highest stations, indeed, there is not much to object to. Roorkee is a fairly representative station of the northern part of the Gangetic plain, and the Mussooree Observatory, situated on the very crest of the ridge of the Himalaya, overlooking the plains, is probably as little affected by the local heating of the ground as any mountain observatory can be. But Dehra, which furnishes the really critical datum of Mr. Hill's reasoning, is on the plain of the *Dún*, a flat valley six or eight miles across, stretching between the Sivaliks and the foot of the Mussooree ridge, and it is by no means self-evident that the local temperature is not largely affected by causes which are quite inoperative in the free atmosphere at the same elevation over the plains.

In our opinion, then, Mr. Hill's conclusion that the storms of April 30 and May 1 were determined by a change in the vertical distribution of temperature, transferring the condition of instability from the lower to the higher atmospheric strata, is at least open to doubt. To a certain extent, indeed, it is supported by the evidence of other observatories in the North-West Himalaya, especially Chakrata, the situation of which is very similar to that of Mussooree; but the difference of their elevation (170 feet) is too small to allow of its having much weight in determining the point at issue.

The most noteworthy feature of the storm of April 30 was the fearful loss of life caused by it at Moradabad. Not less than 230 deaths were reported at this station alone, the vast majority of which were caused directly by the hail. The collector's report states that men caught in the open and without shelter were simply pounded to death. The spring is especially the season of native weddings, and "more than one marriage-party was caught by the storm near the banks of the river and was annihilated." It is, however, suggested by Mr. Hill that many of the deaths may have been caused by cold. "Immediately before the storm the temperature had been very high, and many if not the majority of the deaths due to it may have been occasioned by the persons exposed to its fury being knocked down and temporarily packed in ice." At Moradabad the hailstones are stated to have been the size of plums—probably the *bér* plum, *Zizyphus jujuba*, the cultivated form of which is two or three times as large as a walnut.

In the storm of May 1, the hailstones at some places were larger, though the destruction was less. At Ghaziabad they are said to have been as large as cricket balls, and one was picked up at Delhi weighing 4½ ounces. At Tilhar they are reported to have been larger than goose eggs, and at a neighbouring place they averaged 3 inches in diameter. Their form is described as a flat oval.

SCIENTIFIC SERIALS.

Bulletin de l'Académie Royale de Belgique, November 1889.—On the existence of a gizzard, and on its structure, in the family of the Scolopendridæ, by M. Victor Willem. The presence of a gizzard in the lower organisms was first determined by M. F. Plateau in 1876. But the gizzard of insects was long supposed to be merely a triturating organ acting mechanically, without any physiological function. Continuing Plateau's researches, M. Willem now finds that the gizzard is not only present in several genera of the Scolopendrid family, but that it is a true digester. The structure is fully described, and illustrated by two plates, on which are figured the gizzards of *Scolopendra hispanica*, *S. cingulata*, *S. heros*, *Scolopocryptops*, *Cryptops punctatus*, and *C. hortensis*. In these last, the apparatus is most highly developed, being even more complicated than amongst the higher order of insects. No explanation is offered of this apparent anomaly.—Unexpected proof of diurnal nutation, and necessity of taking it into consideration in the reduction of observations, by M. F. Folie. The coefficient of diurnal nutation as already approximately determined at 0·01s. by the author's numerous researches, has recently been confirmed in a somewhat remarkable manner by the results of M. Kobold's observations of the Polar star with the meridian circle of Strassburg. The azimuthal errors of this instrument were found to present, not an annual, but a diurnal period, and Kobold's corrections are shown to be illusory, being due to his neglect of the element of diurnal nutation in the reduction of his observations. When this element is taken into account, the results harmonize with those previously arrived at by M. Folie.

SOCIETIES AND ACADEMIES.

London.

Royal Society, Dec. 19, 1889.—"On the Effects of Pressure on the Magnetization of Cobalt." By C. Chree, M.A., Fellow of King's College, Cambridge. Communicated by Prof. J. J. Thomson, F.R.S.

It has long been known, from the classic researches of Dr. Joule, that a rod of iron free from stress increases in length when magnetized in a comparatively weak field. When, however, the strength of the field is continually raised, it has been found by Mr. Shelford Bidwell that the rod ceases to increase in length, and then shortens, so that in a sufficiently strong field the length becomes less than it was originally. It has also been found by Villari, Sir W. Thomson, and others, that when a rod of iron is exposed to successive loadings and unloadings of a given weight in a magnetic field, there appears a corresponding cyclic change of magnetization. In this cyclic change the maximum magnetization occurs when the load is "on," or when the load is "off," according as the field is weaker or stronger than a certain critical field depending on the load, called by Sir W. Thomson the Villari critical field.

Cobalt has been found by Mr. Shelford Bidwell to shorten when magnetized in weak fields, but to lengthen in very strong fields. The field in which it ceases to shorten is very much higher than the field in which iron ceases to lengthen. Also in weak fields Sir W. Thomson has found the magnetization of a cobalt rod under cyclic applications of tension to be least when the tension is "on."

Now, Prof. J. J. Thomson has shown that on dynamical principles the effect of changes of magnetization on the length of a rod of magnetic metal, and the effect of changes in the length of the rod on the magnetization, must be fundamentally connected. In his "Applications of Dynamics to Physics and Chemistry," he has arrived at mathematical equations connecting the two phenomena, such that from a knowledge of the one set of phenomena the character of the other set can be deduced.

The conclusions derived from the theory are in the case of iron in accordance with the results of experiment, at least in their general character. In cobalt there is also an agreement between theory and experiment, so far as Sir W. Thomson's experiments go. In the absence of further experiments it would, however, be impossible to tell whether or not this agreement extended to the strong fields in which occurred the important phenomena observed by Mr. Shelford Bidwell. The application of Prof. J. J. Thomson's formulæ to Mr. Shelford Bidwell's results led him to the conclusion that under cyclic applications of pressure a cobalt rod should experience cyclic change of magnetization, and that the maximum magnetization should answer to pressure "on," or to pressure "off," according as the magnetic field was weaker or stronger than a critical field, corresponding to the Villari field in iron. It was for the purpose of determining whether such a critical field did actually exist that the present investigation was commenced at Prof. J. J. Thomson's suggestion.

Employing the magnetometric method, it was found that the agreement between theory and experiment was at least as satisfactory in cobalt as in iron. The application of pressure-cycles in a magnetic field led to a cyclic change of magnetization in a cobalt rod, in which the maximum magnetization occurred when pressure was "on," or when it was "off," according as the strength of the field was below or above 120 C.G.S. units. This accordingly was the Villari critical field foreshadowed by theory.

In weak fields the first pressure applied after the introduction of the cobalt rod into the magnetizing coil caused a large increase in the induced magnetization. As the strength of the field was raised, this change in the magnetization attained a maximum, then, diminishing, vanished in a field considerably stronger than the Villari field for the cyclic effect, and in all stronger fields consisted in a diminution of magnetization.

Both Villari and Prof. Ewing observed that, after the break of the magnetizing current, cyclic changes of tension produced

eventually, in iron wires, cyclic changes of the residual magnetization. In these, the maximum magnetization answered, as in the induced magnetization in fields below the Villari point, to tension "on."

In the present investigation, the existence of a cyclic change in the residual magnetization of cobalt accompanying cyclic changes of pressure has been established, and the magnitude of the effect examined in a large number of fields, extending from 0 to 400 C.G.S. units. It was found that not only the magnitude, but the sign even, of the effect depended largely on the condition of the rod during the break of the current. When the rod was under pressure during the break, the residual magnetization in the cyclic state showed a maximum under pressure, whatever was the strength of the pre-existing field. When, however, the rod was free from pressure during the break of the current, it was only in the residual magnetization left after the weakest fields that the maximum answered to pressure "on." When the strength of the pre-existing field was raised, the effect passed through the value zero and changed sign.

"On the Extension and Flexure of Cylindrical and Spherical Thin Elastic Shells." By A. B. Basset, M.A., F.R.S.

The method which I have employed in dealing with problems relating to the equilibrium and motion of thin cylindrical and spherical elastic shells, is as follows:—

Taking the case of a cylindrical shell, let OADB be a small curvilinear rectangle described on the middle surface, of which the sides OA, BD are generators, and the sides AD, OB are circular sections. The resultant stresses per unit of length across the section AD are completely specified by the following five quantities, viz. (1) a tension, T_1; (2) a tangential shearing stress, M_2; (3) a normal shearing stress, N_2; (4) a flexural couple, G_2; (5) a torsional couple, H_1; and the stresses across BD may be derived by interchanging the suffixes 1 and 2. If, therefore, we resolve all the forces which act upon the element along OA, OB and the normal, and take moments about these lines, we shall obtain the six equations of motion in terms of these stresses.

The expression for the potential energy is next found, which differs from that obtained by Mr. Love (Phil. Trans., 1888), owing to the fact that he has omitted to take into account several terms involving the product of the extensions and the cube of the thickness.

The variational equation can now be written down, and if it be applied to a curvilinear rectangle bounded by two lines of curvature and worked out in the usual way, the line integral part will determine the values of the edge stresses T_1, T_2, ... in terms of the displacements; and the surface integral part will determine the three equations of motion in terms of the displacements. These results furnish a test of the accuracy of the work, and also of the fundamental hypothesis upon which the theory is based (viz. *that if the surfaces of the shell are not subjected to any surface pressures or tangential stresses, the three stresses, R, S, T, are of the order of the square of the thickness*); for if we substitute the values of the edge stresses in the last three of our original equations, they ought to reduce to identities; whilst if we substitute these values in the first three, we ought to reproduce the equations of motion which we have obtained by means of the variational equation; and this is found to be the case.

The boundary conditions are obtained by Stokes's theorem, which enables us to prove that it is possible to apply a certain distribution of stress to the edge of a thin shell, without producing any alteration in the potential energy due to strain.

Geological Society, December 18, 1889.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—On the occurrence of the genus *Girvanella*, and remarks on Oolitic structure, by E. Wethered. The author referred to his previous work, wherein he had shown that *Girvanella* is not confined to Silurian rocks, and that as a rock-forming organism it is more important than was supposed, occurring in the Gloucestershire Pea-grit, and also in the Coralline Oolite of Weymouth. He now dealt more in detail with its occurrence (1) in the *Carboniferous Oolitic Limestone*; and (2) in the *Jurassic Oolites*. In the Carboniferous limestone of the Avon valley, Oolitic limestone occurs on four horizons, in three of which the Oolites rest on dolomite. In none of these three cases are there signs of *Girvanella*. From beds partly Oolitic, and not resting on dolomite, he has been able to determine two new species. The Oolite not associated with dolomite is less crystalline, and the original structure is better preserved. In referring to *G. pisolitica*, he discussed whether *Girvanella* is most allied to the *Challenger* Foraminifer, *Hyperammina vagans*, or to *Syringammina fragilissima*. Traces of the organism occur in the *Clypeus*-grit, but none are quoted from beds of the Great Oolite, nor from the Portland Oolite. The author had already shown that the pisolites in the Coralline Oolite of Weymouth were not concretions, but forms of *Girvanella*. Excluding these, he showed that the spherules are of four types, of which one is the ordinary Oolitic granule, while each of the others suggests the presence of *Girvanella*. The characters of the genus, as seen under the microscope were indicated, and four new species were described. The President remarked on the importance of investigating the question whether these appearances are organic or not. We should take warning from *Eozoon* as to possible differences of opinion in the interpretation of tubular structure, though these mystifying appearances seem more common in serpentine and chalcedony than in calcite. In the bodies depicted, the wall, the irregularity, and the manner in which the tubes curve round each other are in favour of their being organic. Prof. Rupert Jones thought that these forms were not due to mineral but to organic laws. Dr. Evans, while disclaiming any special knowledge of the subject, suggested that the appearances might be interpreted on the supposition of an organism boring into a comparatively hard substance. Dr. Hinde, who had seen most of the known species of *Girvanella*, spoke of the wide distribution of these organisms. Remarks were also offered by Dr. Hicks, Prof. Bonney, Prof. Judd, the Rev. H. H. Winwood, and the author.—On the relation of the Westleton Beds or "Pebbly Sands" of Suffolk to those of Norfolk, and on their extension inland, with some observations on the period of the final elevation and denudation of the Weald and of the Thames Valley, Part 2, by Prof. Joseph Prestwich, F.R.S.—The author having, in the first part of this paper (Proc. Geol. Soc., June 5, 1889), discussed the relationship of the Westleton Beds to the Crag series and to the Glacial deposits, proceeded in the present contribution to consider the extension of the Westleton Beds beyond the area of the Crag, and described their range inland through Suffolk, East, West, and South Essex, Middlesex, North and South Hertfordshire, South Buckinghamshire, and North and South Berkshire, noticing their relationship to the overlying Glacial beds, where these were developed, and the manner in which they reposed upon older deposits. He gave an account of the heights of the various exposures above Ordnance Datum, and mentioned the relative proportion of the different constituents in various sections, thus showing that in their southerly and westerly extension they differed both in composition and in mode of distribution from the Glacial deposits. Distinction was also made between the Westleton Beds and the Brentwood Beds. Attention was next directed to the occurrence of the Westleton series, south of the Thames, in Kent, Surrey, and Hampshire, and their possible extension into Somersetshire was inferred from the character of the deposits on Kingsdown and near Clevedon. In tracing the deposits from the east coast to the Berkshire Downs, the author noticed that at the former place the beds lay at sea-level, but ranging inland, they gradually rose to heights of from 500 to 600 feet; that in the first instance they underlay all the Glacial deposits, and in the second they rose high above them, and their seeming subordination to the Glacial series altogether disappeared; thus at Braintree, where the Westleton Beds were largely developed, they stood up through the Boulder-clay and gravel which wrapped round their base, whilst further west, where they became diminished to mere shingle-beds, they attained heights of from 350 to 400 feet, capping London-clay hills, where the Boulder-clay lay from 80 to 100 feet lower down the slopes, the difference of level between the two deposits becoming still greater in a westerly direction, until finally the Boulder-clay disappeared. The origin of the component pebbles of the beds was discussed, and their derivation traced (1) to the beds of Woolwich age in Kent, North France and Belgium, and possibly to some Diestian beds, (2) to the older rocks of the Ardennes, (3) to the Chalk and older drifts, and (4) to the Lower Greensand of Kent and Surrey, or in part to the Southern drift. The marine nature of the beds was inferred from the included fossils of the type-area, and the absence of these elsewhere accounted for by decalcification. The southward extension of the beds was shown to be limited by the anticlinal of the Ardennes and the Weald, and the scanty palæontological evidence of the nature of that land was noted, and the possible existence of the Scandinavian ice-sheet to the north was referred to in connection with the disappearance of the

beds in that direction. From the uniform character of the Westleton shingles, the author maintained that they must originally have been formed on a comparatively level sea-floor, and that the inequalities in distribution had been produced by subsequent differential movement to the extent of 500 feet or more to the north and west above that experienced to the east and south, where the chronological succession remained unbroken, also that the inequalities below the level of the Westleton beds had been produced since the period of their deposition, as, for instance, the gorge of the Thames at Pangbourne and Goring, and most of the Preglacial valleys in the district; furthermore, evidence was adduced in favour of the formation of the escarpments of the Chalk and Oolites since Westleton times, whilst certain observations supplied data for estimation of the relative amounts of pre- and post-glacial denudation of the valleys. It was stated, in conclusion, that the time for the vast amount of denudation was so limited that it was not easy to realize that such limits could suffice, but the author did not see how the conclusions which he had arrived at could well be avoided. After the reading of this paper there was a discussion, in which the President, Mr. Topley, Prof. Hughes, and others took part.

Linnean Society, December 19, 1889.—Mr. J. G. Baker, F.R.S., Vice-President, in the chair.—Prof. P. M. Duncan made some supplementary remarks on a specimen of *Hyalonema Sieboldii*, which he had exhibited at a previous meeting.—Mr. W. Hatchett Jackson exhibited and gave an account of an electric centipede (*Geophilus electricus*), detailing the circumstances under which he had found it at Oxford, and the results of experiments which he had made with a view of determining the nature and properties of a luminous fluid secreted by it. This, he found, could be separated from the insect, and could be communicated by it to every portion of its integument. An interesting discussion followed, in which Mr. Briese, Mr. A. W. Bennett, Prof. Stewart, Mr. A. D. Michael, Dr. Collingwood, Mr. Christy, and Mr. J. E. Harting took part. The last-named speaker pointed out that the observations made by Mr. W. Hatchett Jackson on this centipede had been long ago anticipated by Dr. Macartney in an elaborate paper on luminous insects published in the Philosophical Transactions for 1810 (vol. c. p. 277).—A paper was then read by Mr. T. Johnson on *Dictyopteris*, in which he gave a detailed account of the life-history of this brown seaweed, with remarks on the systematic position of the *Dictyotaceæ*. Dr. Scott, Mr. George Murray, and Mr. A. W. Bennett criticized various portions of the paper, and acknowledged the important scientific bearing of the facts which had been brought out by Mr. Johnson's careful and minute researches.—In the absence of the author, Mr. W. P. Sladen detailed the more important portions of a paper by the Rev. John Gulick, on intensive segregation and divergent evolution in land Mollusca; a paper which might be regarded as a continuation and amplification of the views which the same author had expressed in a former paper published in the Society's Journal last year (vol xx., Zool., pp. 189-274).

PARIS.

Academy of Sciences, December 30, 1889.—M. Hermite in the chair.—List of the prizes awarded to successful competitors in the various branches of science during the year 1890:—*Geometry*: Prix Francœur, M. Maximilien Marie; Prix Poncelet, M. Édouard Goursat. *Mechanics*: Extraordinary Prize of 6000 francs, MM. Caspari, Clauzel, and Degouy, 2000 francs each; Prix Montyon, M. Gustave Eiffel; Prix Plumey, M. Widmann. *Astronomy*: Prix Lalande, M. Gonnessiat; Prix Valz, M. Charlois; Prix Janssen, Mr. Norman Lockyer. *Physics*: Prix L. La Caze, M. Hertz. *Statistics*: Prix Montyon, two prizes awarded—one to the late M. Petitdidier and M. Lallemand, the other to Dr. F. Ledé. *Chemistry*: Prix Jecker, MM. A. Combes, R. Engel, and A. Verneuil; Prix L. La Caze, M. F. M. Raoult. *Geology*: Prix Delesse, M. Michel Lévy. *Botany*: Prix Desmazières, M. E. Bréal; Prix Montagne, MM. Ch. Richon and Ern. Roze; Prix Thore, MM. de Bosredon and de Ferry de la Bellone. *Agriculture*: Prix Vaillant, M. Ed. Prillieux. *Anatomy and Zoology*: Grand Prize of the Medical Sciences, MM. L. Félix Henneguy and Louis Roule. *Medicine and Surgery*: Prix Montyon, three prizes were awarded to M. A. Charrin, to MM. A. Kelsch and P. L. Kiener, and to M. Basile Danilewsky, respectively; Prix Bréant, M. A. Laveran; Prix Barbier, MM. M. E. Duval, Ed. Heckel, and F. Schlagdenhauffen; Prix Godard, M. A. Le Dentu; Prix Lallemand, M. Paul Loye; Prix Bellion, MM. F. Lagrange, and Laborde and Magnan; Prix Mège, Dr. A. Auvard. *Physiology*: Prix Montyon, M. A. d'Arsonval; Prix L. La Caze, M. François Franck; Prix Pourat, Dr. Johannes Gad and Dr. J. F. Heymans; Prix Martin-Damourette, M. J. V. Laborde. *Physical Geography*: Prix Gay, M. Drake del Castillo. *General Prizes*: Prix Montyon (Unhealthy Industries), honourable mention of Dr. Maxime Randon; Prix Trémont, M. Jules Morin; Prix Gegner (Physiology), M. H. Toussaint; Prix Petit d'Ormoy (Natural Sciences), M. Jean Henri Fabre; Prix Petit d'Ormoy (Mathematical Sciences), M. Paul Appell; Prix Leconte (Chemical Explosives), M. Paul Vieille; Prix Laplace, two prizes, *ex æquo*, to MM. E. A. A. Verlant and E. Ch. E. Herscher.—The following prizes were proposed for the year 1890:—Grand Prize of the Mathemathical Sciences: To perfect in any important point the theory of differential equations of the first order and of the first degree. Prix Bordin: To study the surfaces whose linear element may be reduced to the form

$$ds^2 = [f(u) - \phi(v)](du^2 + dv^2).$$

Prix Francœur: Inventions or works tending to the progress of pure and applied mathematics. Prix Poncelet: The author of any work tending most to further the progress of pure and applied mathematics. Extraordinary Prize of 6000 francs: Any improvements tending to increase the efficiency of the French naval forces. Prix Montyon: Mechanics. Prix Plumey: Improvement of steam-engines or any other invention contributing most to the progress of steam navigation. Prix Lalande: Astronomy. Prix Damoiseau: To perfect the theory of the long periodical irregularities in the movement of the moon caused by the planets. Prix Valz: Astronomy. Prix Janssen: Physical Astronomy. Prix Montyon: Statistics. Prix Jecker: Organic chemistry. Prix Fontannes: The author of the best work on palæontology. Prix Vaillant: Researches on the agencies that have caused the foldings in the terrestrial crust—part played by horizontal displacements. Prix Gay: Orographic study of any mountain system by new and rapid processes. Prix Barbier: Any valuable discovery in the surgical, medical, or pharmaceutical sciences, and in therapeutic botany. Prix Desmazières: The best work on the whole or any part of the Cryptogamic flora. Prix Montagne: The authors of important works on the anatomy, physiology, development, or description of the lower Crytogamic plants. Prix Thore: Works on the cellular Cryptogams of Europe, and on the habits or anatomy of any species of European insect, alternately. Prix Bordin: Comparative study of the auditory nerve in mammals and birds. Prix Savigny: For young zoological travellers. Prix Serres: On general embryology applied as far as possible to physiology and medicine. Prix Dusgate: The best work on the diagnosis of death, and on the means of preventing premature burials. Prix Montyon: Medicine and surgery. Prix Bréant: The discovery of a certain cure for Asiatic cholera. Prix Godard: On the anatomy, physiology, and pathology of genito-urinary organs Prix Lallemand: Researches on the nervous system in the widest sense of the term. Prix Bellion: Works or discoveries serviceable to the health of man or to the improvement of the human species. Prix Mège: The author of a continuation and completion of Dr. Mège's essay on the causes that have retarded or favoured the advancement of medicine. Prix Montyon: Experimental physiology. Prix Pourat: On the properties and functions of the nervous cells attached to the organs of sense or to any one of them. Prix Delalande-Guérineau: For the French traveller or naturalist who shall have rendered the greatest service to France or to science. Prix Jérome Ponti: The author of any scientific work the continuation or development of which may be deemed valuable to science. Prix Montyon: Unhealthy industries. Prix Trémont: For any naturalist, artist, or mechanic needing help in carrying out any project useful or glorious for France. Prix Gegner: In aid of any *savant* distinguished by solid work done towards the advancement of the positive sciences. Prix Laplace: For the best student leaving the École Polytechnique.

BERLIN.

Physical Society, December 20, 1889.—Prof. von Helmholtz, President, in the chair.—Dr. Assmann demonstrated his aspiration thermometers and psychrometers after having first explained the theory and construction of the latter (see NATURE, vol. xxxvii. p. 215, and vol. xl. p. 660). He first dipped one o

the thermometers into warm water at 45° C., in such a way that its external metallic envelopment was in contact with the water and took on the temperature of the latter, while at the same time aspiration could proceed undisturbed. When the clock-work was not set in motion and the turbine in the upper part of the instrument was at rest, the thermometer indicated a temperature of 35° C.; but as soon as aspiration was started by setting the clock-work in motion, the temperature recorded fell to 22°·5 C., being now identical with that indicated by a second thermometer not immersed in water. In the next place, a series of experiments was made in order to determine the rate of flow of the air through the thermometer. To effect this the thermometer was attached by an air-tight joint to the upper end of a glass cylinder whose capacity was 5 litres, whose interior was moistened with soapy water, and whose lower end was closed with a soap-film. On setting the instrument in work the time required for the aspiration of 5 litres of air was measured by the time the soap-film occupied in ascending from the lower to the upper end of the cylinder. The speaker showed that when the turbine was in motion the rate of flow of the aspired air was about 2·5 m. per second; when in addition to the turbine an external injector was used, the velocity rose to rather more than 3 m.; when the injector alone was used the velocity was similarly 3 m. The bellows which he had used in his earlier instruments gave a very variable and much slower current of air. Finally, he demonstrated the action of the instrument when employed as a psychrometer. By surrounding the thermometer with gauze and moistening the latter the instrument recorded a temperature of 18° C., while at the same time a similar non-moistened thermometer recorded 21° C. An ordinary psychrometer which was placed in close proximity to the other indicated 21° C. with the dry-bulb, and 16° C. with the wet. The President pointed out that when determining temperatures with an aspiration thermometer the rarefaction of the air must lead to a slight fall of temperature, which is, however, partly compensated for by the friction of the air. Both these factors can be calculated from the known rate of flow of the air.

In the report of the Berlin Physical Society, NATURE, January 2, p. 215, in the fourth line from the bottom, for "Society" read "Institute."

THE NEW MUZZLING REGULATIONS.

AN essential fault of popular government is in danger of being exemplified just now by the possibility of the selfish interests of a few individuals attracting favourable attention, in utter opposition to the true interests of the nation at large.

A very reprehensible leading article which appeared in the *Standard* on the 4th inst., to which we shall presently refer in fuller detail, has started an agitation in the home counties, especially in Kent, in opposition to the valuable regulations recently issued by Mr. Chaplin against hydrophobia or rabies.

It is not uninstructive to review the way in which the issue of these regulations has been brought about, while it is a matter of painful interest to compare our position in England, as regards the prevalence of rabies, with that of some of the more advanced nations on the Continent.

Before M. Pasteur began his wonderful researches into rabies, the vast majority, even of the highly instructed public, regarded hydrophobia as a kind of Divine visitation, and rabies as a form of canine lunacy. Legislation, in the absence of that which has so frequently been called with a double meaning "a healthy despotism," necessarily lagged behind in the arrest of what everyone now knows to be a simple zymotic disease, which, enzootic in England, becomes, by steady increase during every few years of unchecked development, both epizootic and unfortunately epidemic.

The first advance towards rational prevention of the trouble was made in London in 1885-86 by the Chief Commissioner of Police, first by Sir E. Henderson, afterwards by Sir Charles Warren.

The result of their work is well known—namely, the temporary extirpation of rabies in London. In a country with more respect for scientific fact, such a benefit to the community would have been followed by the general establishment of preventive legislation throughout the centres of the disease, so as to arrest it completely; and this having been effected, the adoption of proper quarantine measures would alone of course have been required to free us for ever from the evil by preventing its reintroduction from abroad.

Partly owing to the fact that, until the most wise establishment by the present Government of a General Board of Agriculture, there was no special authority for moving in the matter, no such general action was taken. Lord Cranbrook, however, was earnestly convinced of the importance of the subject, and conferred a lasting benefit on all those interested in it by appointing that Select Committee of the House of Lords whose Report and evidence not only furnished a complete and exhaustive account of rabies, but also strongly emphasized the necessity of the adoption of thorough legislative measures, especially of muzzling, to prevent and eradicate the malady.

In the meanwhile, rabies in dogs, and of course concurrently its fatal attacks on men, steadily increased, until the spring of last year (1889) saw us threatened again in London with an epidemic like that of 1885.

All the large dog-owners and breeders who had experienced the manifest value of the regulations of 1885 called for the reinstitution of the muzzle, and at the present time the *Field*, *Fancier's Gazette*, &c., afford strong proof, in the earnestness of their expressions of satisfaction at the present muzzling order, of the folly of their contemporary who has endeavoured to oppose it.

Of course, as before, a few agitators, trading on the innate selfishness of some natures, and supported by the money of a small band of individuals whose names should be for ever preserved as having sought to work harm to their fellow-creatures, recommenced their irresponsible attacks on the authorities and others for this much-needed sanitary regulation, and it is a recrudescence of this selfish obstruction which the *Standard* has attempted for some (as yet unknown) reason to revive.

An amusing, if degrading feature of such opposition is the constant change of front which the inevitable progress of scientific truth forces upon these people, as their misstatements and ignorance become revealed to the public. At different stages of the agitation, their leaders, Miss Cobbe, "Ouida," and others, have stated with inexplicable self-contradiction, that no such disease as rabies existed, that it was wholly imaginary, that it was rare in England, that the police ran no risks in extirpating it, that the muzzle produced this (non-existent) disease, and so on to the end of the chapter. But while the logical difficulties in which these writers involve themselves must excite amusement, it is a matter of serious regret that they cannot be legally dealt with like other disseminators of false news, such for instance as those who in the wilderness of the "great gooseberry season" cry "'orrible murder" when homicide is *pro tem.* non-existent. The evil done by these latter is indeed small, compared with that of the far graver false statements which we have cited above.

In spite, however, of this flood of misrepresentations the muzzling regulations were enforced in London, and with notable benefit, and by the recent order they have been continued and extended by Mr. Chaplin, so as to cut right at the root of the evil, viz. in all the centres of the disease simultaneously.

It was with the consciousness that this measure would be required by the country of the President of the Board of Agriculture, that the anti-muzzlites made a last effort against it by holding a public meeting. The real nature of this agitation, which had been notorious from the commencement, was then made most amusingly conspicuous. We refer to the fact that this variety of obstruction is in truth only a branch of the anti-vivisectionist agitation, and worthy of such a parent stem. It seems that at the meeting an *amendment in strong support of muzzling* was carried by a majority of something like 80 per cent. The fact of the origin of the Association which had summoned the meeting having been alluded to, the Chairman, the Bishop of Ely, first (we are glad to see) repudiated the idea that he was an anti-vivisectionist, and then went on to say that the anti-vivisectionists had nothing to do with the anti-muzzling agitation. This repudiation on the Bishop's part was followed by the resignation of the originators of the movement, Miss Cobbe and others, demonstrating the truth of what we have just said and the inaccuracy of the Bishop's second statement.

The general facts bearing upon the origin and development of the agitation were fully exposed at the meeting,

so that the strong expression of opinion in favour of the muzzling regulations (in conjunction with the disingenuousness of the argument of their opponents) is easily understood.

From a survey of the known behaviour of animals affected with rabies, and in accordance with the measures customarily adopted in dealing with infection among animals, where as in the present case it is not desirable to interfere with their free movement from place to place, Mr. Chaplin declared a number of counties as infected, taking areas around to provide sufficient margin against conveyance of contagion.

It is this wise and carefully-designed attempt to stamp out the disease, which the *Standard*, alone in the Press, has attacked in the most unmeasured language. Having the scientific and medical stand-point, the editor through his leader-writers abuses his opponent's attorney (if Mr. Chaplin will forgive the simile). The Conservatives in Kent are positively called upon by the leading daily paper of their party to vote against their own Government, and why? Because they are asked to help stamp out rabies; and at what cost? it may be asked. None save that of the hire of a muzzle.

This is where the difficulty of our kind of Government arises. Because a solitary voice in the Press objects to a sanitary measure, which has nothing whatever to do with politics, ill-feeling is to be aroused among the voters. It is, however, satisfactory to add that possibly no such attempt on the part of any journal has ever met with such a chilling reception from the rest of its contemporaries—those who have not refrained from observations on the matter having only mentioned it to utterly condemn it.

A sanitary question, to our mind, becomes a question of moral right or wrong when the means proposed for its solution involve nothing beyond a little reasonable trouble, and it is this view of the matter which we fancy finally crystallizes out in the form of what is called public opinion. After the process of the actual experience of the last five years, public opinion is evidently set in the direction of preventing hydrophobia by muzzling. It is of course impossible that Mr. Chaplin should yield to this, the first abusive attack that has been made upon him in his official capacity, but certainly if anything should support him, it is the cognizance of the unworthiness of the opposition which the *Standard* has fomented against his action in the service of the community.

We should wish in conclusion to direct attention to certain obvious deductions which can justly be drawn from the history of this matter, and other events connected with the subject of rabies.

Both the prevention and the cure of this horrible zymotic malady are the outcome of close scientific experimental work. It was reserved for M. Pasteur to make clear and harmonize the various stages (always obscure and apparently contradictory at first) of our knowledge by the immense progress he inaugurated and carried out in the study of infection.

It is M. Pasteur who himself has pointed out better than anyone how the disease can be prevented from attacking man or animals, and he is the first who has shown in the slightest degree how it can be prevented from developing in the system after it has gained access to the body.

The nineteenth century, however, affords no shelter to the man of science to discover benefits for his fellowmen, for although the progress of knowledge has fortunately destroyed the Inquisition, yet society tolerates the existence of the anti-vivisectionist agitation, which not only scatters broadcast the foulest and falsest aspersions on such a man's life and character, but in its most recent development violently opposes the advance of hygiene.

POLYTECHNICS FOR LONDON.

WHETHER or not the London County Council comes to the wise decision to utilize the provisions of the new Technical Instruction Act, it is probable that for the most part Londoners will have to look for intermediate and higher technical instruction to other agencies than rate-aided schools, at all events in the immediate future. In these matters London is in an exceptional position as the capital of the Empire. In the first place, it is the natural home of the Normal Schools of Science and Art which form part of the machinery of the Science and Art Department. And, besides this, it is the centre of greatest activity of the organization of the City and Guilds Institute, whose three model Colleges are all situated within the metropolitan area.

The proportion, however, of the inhabitants of London whose education is affected by these higher institutions is necessarily small. The Government schools are imperial rather than local, and their situation is chosen regardless of the industrial needs of London The Central Institution of the City and Guilds likewise belies its name by its situation at South Kensington. The other two schools of the City and Guilds, at Finsbury and Kennington, have a direct and most important relation to surrounding industries, and keep high the standard of what teaching in applied science and art ought to be. But teaching of this high order is very expensive, though the fees charged may be low, and of recent years a newer and more popular movement has sprung up, aiming at a lower standard of instruction carried on at less cost, and adapted, so far as practicable, to the benefit of the mass of working men.

The best type of such institutions in London is the so-called "Polytechnic" in Regent Street. The basis of the organization is the Young Men's Christian Institute started some years ago by Mr. Quintin Hogg. Round this nucleus he has gradually built up an institution in which evening classes, recreation, and gymnastics have all a part. Under his guidance the Institute has grown to great dimensions, and a number of very largely-attended classes of all kinds are now conducted in the building which for many years was occupied by the "Polytechnic" of the diving-bell and Prof. Pepper. Many of the classes are in general and commercial subjects, but there are science and art classes in connection with South Kensington, technological classes in connection with the City and Guilds Institute, and trade and practical classes in various industries and handicrafts. The greater part are held in the evening, but there are also day classes; and day schools for boys and girls are attached to the institution.

It will be seen that this experiment in technical educa-

tion differs very materially in plan from that of such an institution as Finsbury College. The educational side of the Polytechnic does not form an organized school course so much as a set of classes among which a student may choose, and the standard aimed at is not so high. But there is this obvious advantage in taking the Polytechnic as a model for similar institutions that the instruction, so far as it goes, is far less costly than at Finsbury, being largely subsidized by science and art grants.

The example of the Polytechnic has been recently followed, with a certain amount of success, at the People's Palace in Mile End, where the Drapers' Company have devoted the funds which they have withdrawn from the City and Guilds Institute to building and endowing a school somewhat on the Polytechnic lines.

While these institutions have been developing, the Charity Commissioners have been engaged in pursuance of Mr. Bryce's Act of 1883 in framing a scheme for the application of the funds of the City parochial charities for the benefit of the working classes of greater London. The Commissioners came early to the determination to devote a large proportion of the proceeds of the charities to some educational purpose, and decided further that the main direction of the educational institutions thus established should be technical and industrial.

It is not our purpose to enter at all into the questions that have been raised as to the mode of division of the endowment between secular and ecclesiastical purposes, or the wisdom of tying up the greater part of the disposable funds in perpetuity. There are plenty of keen observers who will make their views felt on these questions; and indeed many champions of other schemes, such as the promotion of open spaces, are already in the field. But we must regard the main object to which the funds will be devoted as practically decided. The Charity Commissioners gave notice of it in their last Report, and little exception seemed then to be taken to the project. Since then large sums of money have been raised by local subscriptions on the faith of the proposal. It is too late now to advocate the application of the main part of the fund to any other object than education, and those who are agitating for such a change are, in our opinion, wasting their powder and shot.

But while the public is easily induced to join in a general outcry which, if it has any justification, certainly comes far too late, it is quite possible that, unless vigilant care is exercised, the final scheme may come into force without those alterations and improvements in detail which seem individually of small importance, but may make all the difference between a good and a bad scheme of technical education for London. The funds handled are far larger than those authorized to be raised for the whole of Wales under the new Intermediate Education Act. It behoves all friends of education to take care that these large endowments are used aright.

Let us glance, then, at the main outline of the scheme so far as it relates to technical education. The Commissioners were instructed under the Act to make provision for the "poorer classes." Consequently any technical schools established or aided under the scheme must aim directly at the benefit of the workman rather than that of the manager.

The Commissioners propose to devote large capital grants to the erection of technical and recreative institutes in various parts of London, somewhat on the model of the Regent Street Polytechnic, and to give a permanent endowment to these institutes, as well as to the Polytechnic and the People's Palace already in existence. Each institute is to be governed under a scheme, devised by the Charity Commission, and is to be subject to the general control of a Central Governing Body of Trustees.

The objects of the institutes are threefold. They are to be social centres, where concerts and entertainments may be given, and where outside clubs and working men's societies may have an opportunity of meeting; they are to include young men's and young women's institutes for social and recreative purposes, open to "young persons" between the ages of sixteen and twenty-five; and lastly, they are to provide for the educational wants of the working classes in the neighbourhood. Libraries, museums, swimming-baths, and gymnasia will form part of the equipment of most of these institutions.

It is with the educational work of these "Polytechnics" that we are here most directly concerned. But their educational and social sides must be very closely linked together, and the success of the classes will largely depend on the success of the institute as a whole. Entrance to the clubs may, under the scheme, be made contingent on entrance to the classes, as is now the case at the People's Palace, though such a course seems to us to be unwise. In any case we must not pass over the social side of the institutes without a word. The Young Men's Institute at the Polytechnic has been a great success, but it has been a growth of time, and it has grown round the nucleus of the Y.M.C.A. The social Institute at the People's Palace has sprung suddenly into existence, without the pre-existing nucleus; it is admitted to have been a failure, and is now suppressed. Can the lesson be mistaken? Doubtless the Charity Commissioners are alive to the difficulty. Their detailed regulations for the management of an institute, of which the draft has been published, are, in the main, carefully drawn. But those who hope that the scheme will result in the growth of a number of Palaces of Delight which will delight Mr. Walter Besant's heart will be doomed to disappointment. There will be no People's Palaces"—only "*Young* People's Institutes." The present People's Palace will be constrained to confine its membership in future to persons between the ages of sixteen and twenty-five. Why this limitation? We see with pleasure that the Goldsmiths' Company, who are founding an institute at New Cross on somewhat the same model as those proposed by the scheme, have struck out the upper limit. There are far too many of these restrictions in the scheme. For example, smoking and dancing are (the latter with certain specified exceptions) forbidden. Surely details such as these can be left to the by-laws of the several institutes. Here, again, the Goldsmiths' Company have shown themselves in advance of the Charity Commission.

We have a similar criticism to make on the whole of the educational scheme. There is too little guidance in matters of principle, too much restriction in matters of detail.

Perhaps the most important thing to ensure is that the Central Governing Body shall be a strong body, exercising effective supervision over the teaching of the various

institutes. Its official name ("Trustees of the City Parochial Charities") is unfortunate; it has too much of a flavour of Mr. Bumble's "porochial" office. It would require an Act of Parliament to change the name, so the best thing to do is to let it be forgotten. The Central Governing Body (for so let us call it) is to be representative of the Crown, the City Corporation, the County Council, the higher Colleges and University of London, the Ecclesiastical Commissioners (temporarily), and the Governing Bodies of the Bishopsgate and Cripplegate Foundations. No one can forecast the action of such a hybrid body until we know the actual men who are to be nominated. A very efficient educational body might be elected as proposed, and on the other hand it mightn't. It is to be hoped that one of the blots on the constitution of the Board—the absence of working-men representatives—will be partly corrected by the inclusion of some working-men leaders among the five Crown nominees. But it is impossible to resist the conviction that the suggested constitution—suitable enough to the time when the Act was passed and London had no organized system of local government—has far too little of the popular element, and that it would be far better to put the whole management of the scheme in the hands of the County Council, or a joint committee of the County Council and School Board.

Supposing that the Central Body is all that could be wished, the next thing to ensure is the satisfactory composition of the governing bodies of the various institutes, and their organic connection with the Central Body. It is essential that the schemes shall be so arranged that the educational programme of all the institutes shall pass through the hands of competent experts, and the educational work shall be adequately supervised, inspected, and revised, from time to time. The Charity Commissioners propose two methods of attaining this result. They give three nominations on each governing Board to the Central Governing Body, and these three members may be experts, though of this there is no guarantee. Further, the secretary of each institute is required to send to the secretary of the Central Governing Body a complete list of proposed classes a week before each term. This is presumably intended to give a power of suggestion, if not revision, to the Central Body, but what is the use of suggestions a week before term? What is wanted is a central committee of well-known experts to advise the Central Governing Body on educational matters. The committee should be small—say three scientific and three artistic representatives. They should be paid for their services, and should be in touch with the science and art divisions of every institute.

There is nothing in the scheme to prevent the appointment of such a Committee, though it would be well if some distinct suggestion of the kind were made. In any case it is a matter to be borne in mind and pressed when the time comes, for it may make all the difference in the world to the future of technical education in London. Let us be frank about the matter. How many men are likely in any given district to be on the governing body of the local institute who know the difference between good teaching and bad? And yet no scheme, however admirably drawn, will produce a good technical school, unless it is worked by such men. On the other hand, with a first-rate governing body we have little fear. Payment by results will lose most of its terrors if those in power know the difference between the incompetence which *cannot* earn grants, and the independence which prefers real teaching to cram. And we may add that it is only by associating with the governing body members engaged in local industries that the practical character of the trade classes can be assured.

So much for the machinery. We must next say a word about the character of the instruction to be aimed at in the institutions. It is to be mainly technical, and hence must be adapted to the special needs of each locality. It is by this time a truism to say that this adaptation will not be brought about by allowing a set of science and art teachers to take the line of least resistance through the South Kensington Directory to the goal of the maximum of grant. A lady is reported to have lately obtained a silver medal for agriculture at a London institution which the Charity Commissioners are proposing to endow. Is this adaptation to local needs and industries?

We wish sincerely that those responsible for the whole scheme had been able to arrange for exceptional treatment of the new institutes in the matter of the apportionment of the Government grant now paid on results. No better opportunity is likely to present itself for an experiment in basing grant on efficient inspection rather than on examination. But what chance is there of such a proposal when our Government departments responsible for public education are cut up into air-tight compartments without connection among themselves? The Charity Commission, the Education Department, and the Science and Art Department still form a great circumlocution office, and until this is altered abuses will continue, which it is nobody's business to remedy. Our great hope, therefore, depends on the choice of the principals, teachers, secretaries, inspectors, and governing bodies, who will make or mar the institutes through which, for many years, Londoners will derive their technical instruction. Let them be enlightened men, with broad views and sympathies, who know their business, or at least know their limitations, and all may be well. But if not, it were better that the whole scheme were put in the fire.

What, again, is to be the scope of the instruction? Is it to be mainly confined to the level of "elementary" science and "second-grade" art? Or are there to be advanced classes in more specialized subjects? Provision is made for such classes in the scheme if they can be arranged without trenching on the endowment. The Commissioners are probably afraid of misapplying funds intended for the poor to the benefit of the middle classes. There is justice in their objection, but such instruction can never be made self-supporting, and it is most important that it should be included in the programme of the institutes, if only to keep the standard high throughout. Here is then an opportunity for the City and Guilds Institute. Let it relieve itself of the charge of its examinations, which may now be transferred on equitable terms to the Science and Art Department under the provisions of the Technical Instruction Act, and let it also transfer to the Government the Central Institution, the geographical situation of which marks it out plainly as an adjunct rather than a rival to the Normal School, and let it apply the energy thus liberated in establishing in every "Poly-

technic" a higher department, providing for the more specialized wants of each locality. This will be a work which no body is so well fitted to undertake as the great Institute which has been a pioneer in higher technical instruction. Such, it appears to us, is the true solution of the question of the relations between the Charity Commissioners' scheme and the City and Guilds of London.

One word of caution in conclusion. The new institutes should be allowed to grow, and not be started on too ambitious a scale at first. Local wants change, and the institutes should develop in harmony with their changes. This is the lesson of the old Mechanics' Institutes and Athenæums. The lesson is repeated in the newer experiments of Mr. Hogg's Polytechnic, and the People's Palace. We do not want to begin with erecting huge shells of bricks and mortar, hoping that life will somehow come into them after a time. The life first, then the buildings, to grow as it expands and deepens—that surely is the law of nature. "Several architectural white elephants" is the dismal but suggestive forecast of a writer in the *Charity Organization Review*, on the supposition that this law is violated. If these warnings are neglected, the promoters of the movement will be merely courting failure, however good their intentions may be. And they will have failed because "they were not poets enough to understand that life develops from within."

ASSAYING.

Text-book of Assaying. By C. Beringer and J. J. Beringer. (London: Griffin and Co., 1889.)

THIS text-book marks an important departure in the literature of assaying. The authors abandon the dreary details of traditionary methods, and attempt with success to rationalize the art of the assayer, rather than to follow the usual course of reproducing "dry" assay methods and elaborate classifications of processes the interest of which is only historical. Assaying is here treated, in a broad sense, as the determination, by analytical methods, of components of ores and of intermediate or finished metallurgical products. Such compounds may be either of value in themselves, or important from being valuable or injurious in the operations of smelting, or in adapting the metals for use.

The methods of the authors, and the measure of success which they have attained, may be fairly judged by their treatment of copper, lead, and iron. Copper ores and furnace materials are still sold in the English market by the "Cornish" assay. This antiquated method of assaying has really no claim to retention, now that more trustworthy methods are well known, and the authors give it but little prominence. They, however, repeat the fallacious argument of its apologists by stating that "it gives the purchaser an idea of the quantity and quality of the metal that can be got by smelting." The Cornish assay does not deserve even this modified approval, as the results it affords neither represent the actual amount of copper contained in the ore, nor the proportion of metal which can be produced by smelting, and several expert assayers, working on portions of the same samples, will obtain results which vary in the most erratic way. Fortunately for those who may be guided by this text-book, its authors proceed to describe assaying processes which are really well calculated to give trustworthy indications as to the quantity and quality of metal obtainable from ores. These are to be found in well proved "wet" methods of determining actual copper contained in ores as well as the components that interfere with the extraction and the quality of the metal. In describing these methods, ample information is given for the guidance of the smelter under the varying conditions of the metal's occurrence. While passing shortly over the Cornish assay, the authors judiciously omit such clumsy "wet" methods of assay as the direct titration by cyanide of potassium, which is retained in some recent books of standing, although it has been abandoned by most skilful assayers. On the other hand, titration by cyanide of potassium after separation of the copper from interfering metals, and the assay by electrolysis, leave little to be desired in rapidity and accuracy, and to these due prominence is given. Failing reasonable manipulative skill, no assay can be accurate, and the expertness demanded by those who conduct the "dry" or Cornish assay is not more easily acquired than is the analytical skill needed for better "wet" methods. In an assay method giving accurately the amount of metal actually present in the ore, the metallurgist has a sure basis for calculation, the results of which can be brought under the control of his experience as to the losses of metal in operations on a large scale. The results of the Cornish assay, with all its inherent uncertainty, have equally to be judged in the light of the smelter's experience as to what the final "out-turn" will be. In lead, again, the dry assay is usually treated in books on assaying with much elaboration, which is no longer useful, if it ever was. It gives results that indicate neither the actual amount of metal contained in the ore, nor the amount which will be produced by smelting, and like the Cornish assay for copper is most unsatisfactory for guidance in smelting. The wet methods of lead assaying which are described are convenient and trustworthy, while the only practically useful methods of dry lead assay are given in sufficient detail. In the assay of iron ores we find dry methods entirely omitted. The wisdom of this cannot be doubted, for the want of exactitude which is characteristic of the dry assay of copper and lead is still more marked in the dry assay of iron. Processes of wet assay capable of giving prompt and strictly accurate results are available, and these are fully described.

The plan of subordinating or ignoring unsatisfactory methods of assay, while giving prominence to those which have proved to be trustworthy, runs through the treatment of methods of assaying the other metals, as well as estimating the components of ores which are not usually dealt with in books on assaying. Among the latter are silica, the earths, sulphur, arsenic, and phosphorus. These demand study by the metallurgist, to whom, under either the necessity of "fluxing" them away, or of minimizing their interference with the purity of the metals, their ready and accurate determination is a matter of the greatest importance. The details of assaying the precious metals, though hardly sufficient for adoption in the assay of bullion in a mint, are all that is needed in a works.

The authors have clearly not been content to merely record published processes, but in order to add to the completeness of their work have given unpublished

results of the experience acquired by themselves and others. The writer notices their description of a process for the estimation of arsenic in minerals and metals, which was devised by himself for use in works under his control, that has not hitherto been published. It consists in the separation of arsenic from its associations, by distillation with ferric chloride mixed with calcium chloride, and subsequent titration of the distillate by iodine. The authors are mistaken in stating that there is a difficulty in obtaining ferric chloride free from arsenic. Even if there were difficulties, it is obvious that the process itself affords a ready means of eliminating arsenic from the ferric chloride mixture, before using it in the actual assay. In this and one or two other cases, there is a tendency to adopt the always undesirable method of "blank" experiments to correct error arising from the use of impure reagents, rather than whenever practicable to avoid the source of danger by the use of pure materials. These are, however, hardly noticeable blemishes in a really meritorious work, that may safely be depended upon by those using it either for systematic instruction or for reference. THOMAS GIBB.

BREWING MICROSCOPY.

The Microscope in the Brewery and Malt House. By Chas. Geo. Mathews, F.C.S., F.I.C., &c., and Francis Edw. Lott, F.I.C., A.R.S.M., &c. (London and Derby: Bemrose and Sons, 1889.)

THERE are certainly few industries the growth and development of which have been more influenced by the progress of pure scientific discovery than those of the brewer and distiller. These industries, formerly carried on upon purely empirical lines, handed down from father to son through countless generations, have in recent years, through the advances in chemical and biological science, been so transformed that their successful conduct at the present time requires a most thorough acquaintance with the leading principles of these sciences. As a consequence of this change, we find an increasing tendency for these industries to become concentrated in a smaller number of hands each producing on a larger and larger scale. The small brewer himself lacking the necessary scientific training, and not able to afford the requisite skilled assistance, gives way before the larger breweries employing a complete scientific staff and provided with the latest improvements.

The present work is, we understand, intended to bring before those connected with brewing a concise account of the assistance which may be derived in the conduct of their business from the use of the microscope. We are of opinion that the authors have been unfortunate already in the choice of their title, as one of the most conspicuous results of modern scientific research in this direction is that the use of the microscope alone is of comparatively little value in the study of micro-organisms in general, whether connected with fermentation or other processes. This inadequacy of microscopic study *per se* the authors in various parts of their work indeed frankly admit. Modern students of these low forms of life have, in fact, become more and more aware of the fallacious results yielded by mere microscopical observation when unaccompanied and uncontrolled by those processes of cultivation which have been developed during the past ten years. Even the work performed under the auspices of the masterly genius and supreme experimental skill of Pasteur has had to be revised and brought up to date by Hansen, with the aid of the more recent methods of research. Now, although the authors appear fully aware of the great change which has taken place since the earlier work of Pasteur, Reess, Fitz, and others, they have not sufficiently distinguished between observations which rest upon the surest foundation and fulfilling the most modern requirements, and those which, though possibly correct, require repetition and confirmation.

The absence of sharp differentiation in this matter cannot fail, we believe, to occasion much confusion in the mind of the ordinary practical student who depends upon text-books and manuals for his guidance and information, and it is, in our opinion, quite unnecessary that he should be burdened with the microscopic descriptions of the various forms of yeast given by the older observers, who were almost certainly dealing with impure cultures, but on the contrary he should rather devote his whole attention to the characters of such undoubtedly pure forms of yeast as have been obtained by the most recent methods. Moreover, unless the necessity of resorting to these cultivation experiments for obtaining accurate information is duly impressed upon the student, he will naturally be inclined to shirk these far more laborious and difficult observations, and place undue reliance upon microscopic features.

These remarks apply, perhaps, with even greater force to the manner in which the authors have dealt with the schizomycetes; in this part of the book we find much space devoted to microscopic descriptions of bacteria of uncertain purity, whilst there is little or nothing said about the methods by which these organisms can be really identified, and their characters defined. We also miss any adequate account of the staining-processes which are so invaluable in obtaining a correct idea of the microscopic forms and dimensions of bacteria. As an instance of the unsatisfactory present condition of brewing microscopy, we may quote the following sentence: "*Bact. lactis*, as seen in beers, is generally in the form of small rods, 2 to 3 μ in length, and sometimes in threads containing from 2 to 5 individuals; it is not certain, however, that this form is *B. lactis*." Thus, in respect of the bacterium which is perhaps of most consequence to the brewer, as being "the most commonly occurring disease-organism encountered in the brewing process" there is this absolute lack of all precise information.

What may be called the more purely scientific part of the work is succeeded by a chapter of "general remarks on the brewing process," which, embodying as it does some of the practical experience of the authors themselves, we would have gladly seen enlarged.

The book, which is printed on excellent paper and elegantly got up, is illustrated with a number of admirably executed plates, many of the best of which are original.

A full index and glossary are appended.

OUR BOOK SHELF.

Flower-Land: an Introduction to Botany. By Robert Fisher, M.A., Vicar of Sewerby, Yorks. (London: Bemrose and Sons, 1889.)

THIS is a capital first book of botany, intended for small children. The style, however, is really more elementary than the matter, and a child who has mastered this book will have made a very good start in the science. There is a good deal of information given about the internal structure and function, as well as the external form, of the organs of plants, and this information is given correctly, as well as clearly.

The book is illustrated by 177 woodcuts, most of which are well suited to their purpose. D. H. S.

Five Months' Fine Weather in Canada, Western U.S., and Mexico. By Mrs. E. H. Carbutt. (London: Sampson Low and Co., 1889.)

IN this book Mrs. Carbutt records her experiences during a remarkably pleasant journey made by herself and her husband in the New World. The scenes she describes have often been described before, but she writes so brightly about what she saw that even readers to whom she has nothing new to tell will find a good deal to interest them in her narrative. They will be particularly pleased with her account of "sunny Mexico, and its merry, courteous people."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Duke of Argyll and the Neo-Darwinians.

IT has a curious and not uninstructive effect to see the pages of this journal invaded by the methods of discussion which are characteristic of political warfare. The letter of the Duke of Argyll, published in NATURE for December 26, 1889 (p. 173) is a clever debating speech. But it rather obscures than illuminates the questions really at issue. And, after the fashion of the political orator, it attributes to those who disagree with the writer motives which, in so far as they differ from reasoned conviction, are essentially insincere.

In politics, the personal rivalry which is bound up inextricably with the solution of great problems may make it a necessary part of the game to endeavour to belittle one's opponents. But in science it is not so. The newer problems which have been raised by Darwinism depend for their solution upon the discussion of evidence, and no competent biologists will, in the long run, be influenced in the opinions they form about them by anything else.

There is nothing in the Duke's letter which has not been worn threadbare by discussion. Still, there are, no doubt, many readers of NATURE who, while taking a general interest in the matter, have not followed all that has been written about it. I am disposed to think, therefore, that it may not be without its use to go over the ground which the letter covers.

First, as to acquired characters. Let us take a simple case. It is admitted that a blacksmith, by the constant use of his arms, may stimulate their abnormal muscular development; that is an acquired character. But a working man, whose arms are of perfectly average dimensions, may nevertheless have a son with arms which would seem to mark him out for the blacksmith's profession; that would be a congenital variation. Now we know that a congenital variation is likely to be inherited; that is a matter of observation. What is the case as to the acquired character? The answer must be, I take it, that there is no probability that the arms of a blacksmith's son will differ in any respect from those of the average inhabitant in the locality where he was born. The Duke of Argyll, however, suggests that there is "no necessary antagonism between congenital variation and the transmission of acquired characters." This is perfectly reasonable; theoretically, there is none. But this does not make the transmission of acquired characters less doubtful. The Duke has no doubt about it, however. "So far from its being unproved, it is consistent with all observation and all experience. It lies at the foundation of all organic development." Very possibly, but where is the observation and where is the experience? These are *the* biological *desiderata* of the day. Imagine the fate at the Duke's hands of any scientific writer who put forward statements such as these unsupported by a shred of a fact.

"This being so," however, the question then arises, Why do extreme Darwinians so fiercely oppose the idea of the transmission of acquired characters? Well, it is obvious that they do so because they think the evidence in its favour insufficient, and it is clearly the duty of a scientific man, whether an extreme Darwinian or not, to oppose the acceptance of that which experience does not support. But the Duke of Argyll attributes their opposition to two causes: first, jealousy of associating the names of Lamarck and Darwin; and, secondly, the dethronement of their idol Fortuity. The first of these reasons is almost too preposterous to discuss. No serious naturalist would speak with other than respect of Lamarck's position in scientific history; this cannot be effaced however much that of Darwin may be magnified. And no serious naturalist would adhere to any theory Darwin had propounded a moment longer than the evidence seemed to carry conviction. The charge in this particular matter is, however, the more grotesque, because, although Darwin did not esteem as of much value Lamarck's doctrine of development and progression, we know that his own mind became more and more fluid on the question of the "direct action of conditions." The idea is in fact so plausible that the difficulty is not in accepting it, but in shaking oneself free from it. What were probably the last words which Darwin wrote on the subject are contained in a letter to Prof. Semper, dated July 19, 1881. I quote a passage which appears to me to pretty accurately define the present position of the question:—

"No doubt I originally attributed too little weight to the direct action of conditions, but Hoffmann's paper has staggered me. Perhaps hundreds of generations of exposure are necessary. It is a most perplexing subject. I wish I was not so old, and had more strength, for I see lines of research to follow. Hoffmann even doubts whether plants vary more under cultivation than in their native home and under their natural conditions ("Life and Letters," vol. iii. p. 345).

Darwin's difficulty, in point of fact, was exactly that of everyone else. The evidence, instead of being "consistent with all observation and all experience," failed to be forthcoming.

The second reason is equally baseless. Fortuity is no idol of the neo-Darwinians; if it is an idol at all, it is an "idol of the market," imposed upon their understanding by the Duke. But at any rate he does not attribute any blame to Darwin. And as this is a rather important matter, on which I admit that persons who ought to know better have gone astray, I will quote a passage on the subject from Prof. Huxley's admirable biography (Proc. Roy. Soc., No. 269):—

"Those, again, who compare the operation of the natural causes which bring about variation and selection with what they are pleased to call 'chance,' can hardly have read the opening paragraph of the fifth chapter of the 'Origin' (ed. 1, p. 131): 'I have sometimes spoken as if the variations . . . . had been due to chance. This is of course a wholly incorrect expression, but it seems to acknowledge plainly our ignorance of the cause of each particular variation.'"

It is obvious that the use of accidental in the guarded sense in which it is employed by Darwin is widely different from fortuitous as employed by the Duke of Argyll. Darwin took variation as a fact of experience. Its causes and laws have still to be worked out. One of the latter, due to Quetelet, was explained by Prof. George Darwin in this journal (vol. viii., 1873, p. 505). He says: "One may assume, with come confidence, that under normal conditions, the variation of any organ in the same species may be symmetrically grouped about a centre of greatest density."

And this is quite in accord with the remark of Weismann that variability is not something independent of and in some way added to the organism, but is a mere expression for the fluctuations in its type. Variation is therefore not unlimited, and we must admit with Weismann that its limits are determined by "the underlying physical nature of the organism;" or as he again puts it, "under the most favourable circumstances a bird

can never be transformed into a mammal." There is something more therefore than blind chance at work here.

But within the limits, it is a matter of experience that every possible variation may occur. If anyone will take the trouble to examine the leaves of the ribbon-grass so commonly cultivated in gardens, he will find it impossible to obtain any pair in which the green and white striping is exactly alike. If it were possible to raise to maturity all the progeny of some prolific organism, the same diversity (in different degree, of course) would manifest itself; but the whole group of variations in respect of any one organ would obey Quetelet's law. When we attempt to give some physical explanation of this fact, we know from the objective facts which have been made out about fertilization that, although the protoplasmic content of the fertilized ovum is, in a general sense, uniform, its actual structure and physiological components must be combined in as endless variety as the green and white stripes of the leaves of the ribbon-grass. If, with Prof. Lankester, we say that the combinations are kaleidoscopic, I do not see that we go beyond the facts. And it appears to me quite permissible to correlate the ascertained variable constitution of the ovum arising from this cause with the equally ascertained varying structure of the organism developed from it.

Of the varied progeny, we know that some survive and others do not. And what Darwin has taught us is, that the reason of survival is the possession of favourable variations. The surviving race necessarily differs somewhat from its progenitors, and Darwin has further stated that it is probable that by the continued repetition of the process all the diversity of organic nature has been brought about.

The area of fortuity is narrowed down therefore, on this point of view, to the variable constitution of the individual ovum. And it is upon the recognition of this fact, for which there seems to be good scientific evidence, that the Duke of Argyll founds his charge that the neo-Darwinians make fortuity their idol. The reason appears to be that it comes into collision with teleological views. But such collisions are no new event in the history of the biological sciences. And teleology, like a wise damsel, has generally, though temporarily ruffled, managed to gather up her skirts with dignity and make the best of it. For some element of fortuity is inseparable from life as we see it. It is at the bottom one of the most pathetic things about it. Nowhere is this more vividly portrayed perhaps than by Addison in the "Vision of Mirzah." Yet I do not remember that anyone was ever so unwise as to taunt Addison with making fortuity his idol.

But, philosophically considered, what is gained by this tenacity about out-works? I reply, exactly as much as was gained by the tenacity of the Church in respect to the geocentric theory of the planetary system. Scientific men cannot be stopped in the application of their best ability to the investigation of Nature. If their conclusions are false, they will detect the falsity; if true, they will not be deterred from accepting them by some *a priori* conception of the order of the universe. It is not justifiable to say that this is due to any devotion to such an empty abstraction as fortuity. No scientific man is, I hope, so foolish as to suppose that, however completely mechanical may be his conception of Nature, he is in any way competent to account for its existence. The real problem of all is only pushed further back. And the Duke of Argyll's difficulty resolves itself into the old question, whether it is more orthodox to conceive of the universe as an automatically self-regulating machine, or as one which requires tinkering at every moment of its action.

It may be replied that this is all very well, but that it is not the way the neo-Darwinians state their case. I may be, therefore, excused for quoting some passages to the contrary from Weismann's "Studies in the Theory of Descent":—

"This conception represents very precisely the well-known decision of Kant: 'Since we cannot in any case know *a priori* to what extent the mechanism of Nature serves as a means to every final purpose in the latter, or how far the mechanical explanation possible to us reaches,' natural science must everywhere press the attempt at mechanical explanation as far as possible" (p. 638).

Further, he quotes from Karl Ernst von Baer:—

"The naturalist must always commence with details, and may then afterwards ask whether the totality of details leads him to a general and final basis of intentional design" (p. 639).

Again, he says:—

"We now believe that organic nature must be conceived as mechanical. But does it thereby follow that we must totally deny a final universal cause? Certainly not; it would be a great delusion if anyone were to believe that he had arrived at a comprehension of the universe by tracing the phenomena of Nature to mechanical principles" (p. 710).

In truth, this revolt of teleology against Darwinism is a little ungrateful. For, if Darwinism has done anything, it has carried on and indefinitely extended its work. In the last century, teleology was, it seems to me, a valuable motive-power in biological research. Such a book as Derham's "Physico-Theology" (1711) may be read with interest even now. I well remember that my first ideas of adaptive structures were obtained from the pages of Paley. Thirty years ago I do not know, except from them and the notes to Darwin's "Botanic Garden," where such information was to be otained. The basis of research was, however, too narrow to continue; it did not look beyond the welfare of the individual. The more subtle and recondite springs of adaptation opened up by the researches of Darwin, which look to the welfare of the race, were not within its purview. Consequently it dried up, and virtually expired with the Bridgewater Treatises.

To return, however, to the Duke of Argyll. "Neither mechanical aggregation, nor mechanical segregation, can possibly account for the building up of organic tissues." Who has said they did? The Duke has entirely misunderstood the matter. Prof. Lankester never suggested that it was possible to put so much protoplasm into a vessel, and shake out a cockatoo or a guinea-pig at choice. His image of the kaleidoscope had nothing to do with the building up of organisms, only with the varied combination of the elements known to take part in the formation of the fertilized ova from which organisms originate.

I am not sure that I perfectly comprehend what follows. Perhaps some further emendation than that already published is needed in one of the sentences. But it seems evident that the Duke is re-stating his old doctrine of "prophetic germs." He has already defined what he means by these (NATURE, vol. xxxviii. p. 564). "All organs," he says, "do actually pass through rudimentary stages in which actual use is impossible." Here, again, as in the case of the transmission of acquired characters, what one wants is not a reiteration of the assertion, but some definite observed evidence. For the production of this, if only in a single instance, Prof. Lankester pressed the Duke more than a year ago (NATURE, *l.c.* p. 588). None, however, has as yet been forthcoming; and it appears to me that it is not permissible to persist in statements for which he does not attempt to offer a shadow of proof.

The Duke exults in a very amazing fashion over what he strangely calls Prof. Lankester's admission that "natural selection cannot account for the pre-existence of the structures which are prescribed for its choice." I am afraid I have already trespassed on your space too much with quotations; but I have done so in order to show, in some measure at any rate, what is the consensus of opinions amongst students of Darwinism; and I must answer the Duke with one more from Prof. Huxley's admirable biography. It is true that the Royal Society publishes these things in the least attractive way possible; but this particular paper could hardly have escaped attention, as it won the notice and admiration of even a journal so little occupied with scientific discussion as *Truth*.

"There is another sense, however, in which it is equally true that selection originates nothing. 'Unless profitable variations . . . occur, natural selection can do nothing' ('Origin,' ed. 1, p. 82). 'Nothing can be effected unless favourable variations occur' (*l.c.*, p. 108). 'What applies to one animal will apply throughout time to all animals—that is, if they vary—for otherwise natural selection can do nothing. So it will be with plants' (*l.c.* p. 113). Strictly speaking, therefore, the origin of species in general lies in variation; while the origin of any particular species lies, firstly, in the occurrence, and, secondly, in the selection and preservation of a particular variation. Clearness on this head will relieve one from the necessity of attending to the fallacious assertion that natural selection is a *deus ex machinâ*, or occult agency."

And the Duke says he has been waiting for this for thirty years. One can only wonder what Darwinian literature has been the subject of his studies during that time.

W. T. THISELTON DYER.

Royal Gardens, Kew, January 6.

The Microseismic Vibration of the Earth's Crust.

IN Mr. White's article on British earthquakes (NATURE, Jan. 2, p. 202) he refers to me as having *discovered* the microseismic

vibration of the earth's crust. My brother Horace and I were, we believe, the first to verify in England the observations of Bertelli, Rossi, d'Abbadie, and the other (principally Italian) pioneers in this interesting subject.

In our Reports to the British Association for 1881 and 1882 on "The Lunar Disturbance of Gravity," some account will be found of the earlier literature on the subject.

January 9. G. H. DARWIN.

Meteor.

ON Sunday, 12th inst., about 8.10 p.m., a bright meteor was seen here, coming into view near δ Aurigæ. It was of a reddish colour, moved slowly, leaving a short tail, and burst above ε Leonis, then with diminished light continued its course to the horizon. T. W. MORTON.

Beaumont College, Old Windsor, January 13.

MAGNETISM.[1]

I.

AS old as any part of electrical science is the knowledge that a needle or bar of steel which has been touched with a loadstone will point to the north. Long before the first experiments of Galvani and Volta the general properties of steel magnets had been observed—how like poles repelled each other, and unlike attracted each other; how the parts of a broken magnet were each complete magnets with a pair of poles. The general character of the earth's magnetism has long been known—that the earth behaves with regard to magnets as though it had two magnetic poles respectively near the rotative poles, and that these poles have a slow secular motion. For many years the earth's magnetism has been the subject of careful study by the most powerful minds. Gauss organized a staff of voluntary observers, and applied his unsurpassed powers of mathematical analysis to obtaining from their results all that could be learned.

The magnetism of iron ships is of so much importance in navigation that a good deal of the time of men of great power has been devoted to its study. It was *the* scientific study of Archibald Smith; and Airy and Thomson have added not a little to our practical knowledge of the disturbance of the compass by the iron of the ship. Sir W. Thomson, in addition to much valuable practical work on the compass, and experimental work on magnetism, has given the most complete and elegant mathematical theory of the subject. Of late years the development of the dynamo machine has directed attention to the magnetization of iron from a different point of view, and a very great deal has been done by many workers to ascertain the facts regarding the magnetic properties of iron. The upshot of these many years of study by practical men interested in the mariner's compass or in dynamo machines by theoretical men interested in looking into the nature of things, is, that although we know a great many facts about magnetism, and a great deal about the relation of these facts to each other, we are as ignorant as ever we were as to any reason why the earth is a magnet, as to why its magnetic poles are in slow motion in relation to its substance, or as to why iron, nickel, and cobalt are magnetic, and nothing else, so far as we know, is to any practical extent. In most branches of science the more facts we know the more fully we recognize a continuity in virtue of which we see the same property running through all the various forms of matter. It is not so in magnetism; here the more we know the more remarkably exceptional does the property appear, the less chance does there seem to be of resolving it into anything else. It seems to me that I cannot better occupy the present occasion than by recalling your attention to, and inviting discussion of, some of those salient properties of magnetism as exhibited by iron, nickel, and cobalt—properties most of them very familiar, but properties which any theory of magnetism must reckon with and explain. We shall not touch on the great subject of the earth as a magnet—though much has been recently done, particularly by Rücker and Thorpe—but deal simply with magnetism as a property of these three bodies, and consider its natural history, and how it varies with the varying condition of the material.

To fix our ideas, let us consider, then, a ring of uniform section of any convenient area and diameter. Let us suppose this ring to be wound with copper wire, the convolutions being insulated. Over the copper wire let us suppose that a second wire is wound, also insulated, the coils of each wire being arranged as are the coils of any ordinary modern transformer. Let us suppose that the ends of the inner coil, which we will call the secondary coil, are connected to a ballistic galvanometer; and that the ends of the outer coil, called the primary, are connected, through a key for reversing the current, with a battery. If the current in the primary coil is reversed, the galvanometer needle is observed to receive a sudden or impulsive deflection, indicating that for a short time an electromotive force has been acting on the secondary coil. If the resistance of the secondary circuit is varied, the sudden deflection of the galvanometer needle varies inversely as the resistance. With constant resistance of the secondary circuit the deflection varies as the number of convolutions in the secondary circuit. If the ring upon which the coils of copper wire are wound is made of wood or glass—or, indeed, of 99 out of every 100 substances which could be proposed—we should find that for a given current in the primary coil the deflection of the galvanometer in the secondary circuit is substantially the same. The ring may be of copper, of gold, of wood, or glass—it may be solid or it may be hollow—it makes no difference in the deflection of the galvanometer. We find, further, that with the vast majority of substances the deflection of the galvanometer in the secondary circuit is proportional to the current in the primary circuit. If, however, the ring be of soft iron, we find that the conditions are enormously different. In the first place, the deflections of the galvanometer are very many times as great as if the ring were made of glass, or copper, or wood. In the second place, the deflections on the galvanometer in the secondary circuit are not proportional to the current in the primary circuit; but as the current in the primary circuit is step by step increased we find that the galvanometer deflections increase somewhat, as is illustrated in the accompanying curve (Fig. 1), in which the abscissæ are proportional to the primary current, and the ordinates are proportional to the galvanometer deflections. You observe that as the primary current is increased the galvanometer deflection increases at first at a certain rate; as the primary current attains a certain value the rate at which the deflection increases therewith is rapidly increased, as shown in the upward turn of the curve. This rate of increase is maintained for a time, but only for a time. When the primary current attains a certain value the curve bends downward, indicating that the deflections of the galvanometer are now increasing less rapidly as the primary current is increased; if the primary current be still continually increased, the galvanometer deflections increase less and less rapidly.

Now what I want to particularly impress upon you is the enormous difference which exists between soft iron on the one hand, and ordinary substances on the other. On this diagram I have taken the galvanometer deflections to the same scale for iron, and for such substances as glass or wood. You see that the deflections in the case of glass or wood, to the same scale, are so small as to be absolutely inappreciable, whilst the deflection for iron at one point of the curve is something like 2000 times as

[1] Inaugural Address delivered before the Institution of Electrical Engineers, on Thursday, January 9, by J. Hopkinson, M.A., D.Sc., F.R.S., President.

great as for non-magnetic substances. This extraordinary property is possessed by only two other substances besides iron—cobalt and nickel. On the same figure are curves showing on the same scale what would be the deflections for cobalt and nickel, taken from Prof. Rowlands's paper. You observe that they show the same general characteristics as iron, but in a rather less degree. Still, it is obvious that these substances may be broadly classed with iron in contradistinction to the great mass of other bodies. On the other hand, diamagnetic bodies belong distinctly to the other class. If the deflection with a non-magnetic ring be unity, that with iron, as already stated, may be as much as 2000; that with bismuth, the most powerful diamagnetic known, is 0·999825—a quantity differing very little from unity. Note, then, the first fact which any theory of magnetism has to explain is: Iron, nickel, and cobalt, all enormously magnetic; other substances practically non-magnetic. A second fact is: With most bodies the action of the primary current on the secondary circuit is strictly proportional to the primary current; with magnetic bodies it is by no means so.

You will observe that the ordinates in these curves, which are proportional to the kicks or elongations of the galvanometer, are called induction, and that the abscissæ are called magnetizing force. Let us see a little more precisely what we mean by the terms, and what are the units of measurement taken. The elongation of the galvanometer measures an impulsive electromotive force—an electromotive force acting for a very short time. Charge a condenser to a known potential, and discharge it through the galvanometer: the needle of the galvanometer will swing aside through a number of divisions proportional to the quantity of electricity in the condenser—that is, to the capacity and the potential. From this we may calculate the quantity of electricity required to give a unit elongation. Multiply this by the actual resistance of the secondary circuit and we have the impulsive electromotive force in volts and seconds, which will, in the particular secondary circuit, give a unit elongation. We must multiply this by 10^8 to have it in absolute C.G.S. units. Now the induction is the impulsive electromotive force in absolute C.G.S. units divided by the number of secondary coils and by the area of section of the ring in square centimetres. The line integral of magnetizing force is the current in the primary in absolute C.G.S. units—that is, one-tenth of the current in amperes—multiplied by 4π. The magnetizing force is the line integral divided

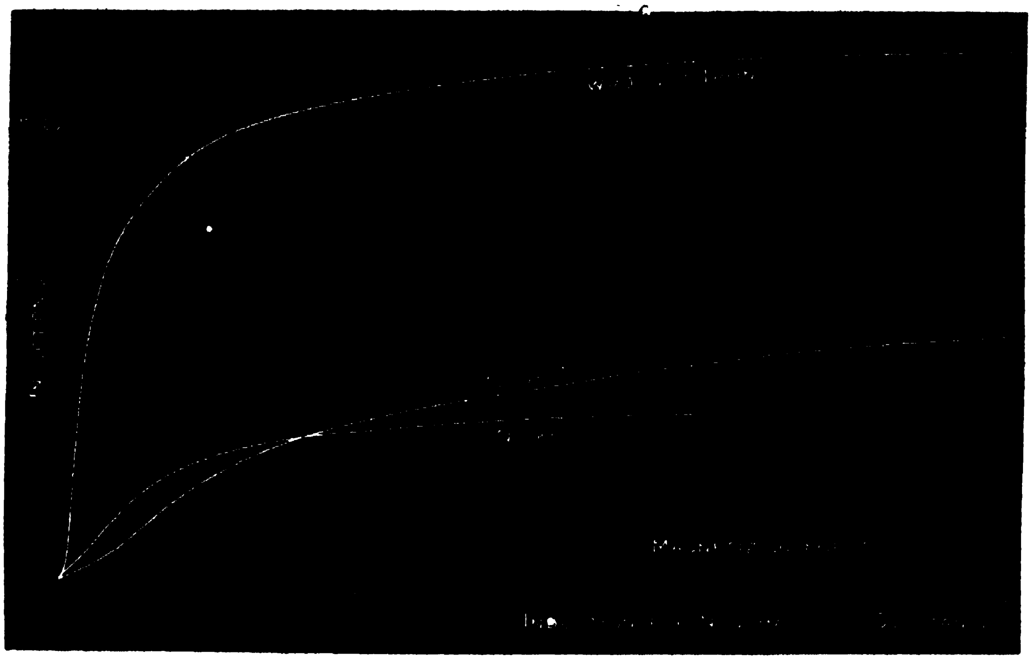

Fig. 1.

by the length of the line over which that line integral is distributed. This is, in truth, not exactly the same for all points of the section of the ring—an imperfection so far as it goes in the ring method of experiment. The absolute electro-magnetic C.G.S. units have been so chosen that if the ring be perfectly non-magnetic the induction is equal to the magnetizing force. We may refer later to the permeability, as Sir W. Thomson calls it; it is the ratio of the induction to the magnetizing force causing it, and is usually denoted by μ.

There is a further difference between the limited class of magnetic bodies and the great class which are non-magnetic. To show this, we may suppose our experiment with the ring to be varied in one or other of two or three different ways. To fix our ideas, let us suppose that the secondary coil is collected in one part of the ring, which, provided that the number of turns in the secondary is maintained the same, will make no difference in the result in the galvanometer. Let us suppose, further, that the ring is divided so that its parts may be plucked from together, and the secondary coil entirely withdrawn from the ring. If now the primary current have a certain value, and if the ring be plucked apart and the secondary coil withdrawn, we shall find that, whatever be the substance of which the ring is composed, the galvanometer deflection is one-half of what it would have been if the primary current had been reversed. I should perhaps say approximately one-half, as it is not quite strictly the case in some samples of steel, although, broadly speaking, it is one-half. This is natural enough, for the exciting cause is reduced from—let us call it a positive value, to nothing when the secondary coil is withdrawn; it is changed from a positive value to an equal and opposite negative value when the primary current is reversed. Now comes the third characteristic difference between the magnetic bodies and the non-magnetic. Suppose that, instead of plucking the ring apart when the current had a certain value, the current was raised to this value and then gradually diminished to nothing, and that then the ring was plucked apart and the secondary coil withdrawn. If the ring be non-magnetic, we find that there is no deflection of the galvanometer; but, on the other hand, if the ring be of iron, we find a very large deflection, amounting, it may be, to 80 or 90 per cent. of the deflection caused by the withdrawal of the coil when the current had its full value. Whatever be the property that the passing of the primary current has imparted to the iron, it is clear that the iron

retains a large part of this property after the current has ceased. We may push the experiment a stage further. Suppose that the current in the primary is raised to a great value, and is then slowly diminished to a smaller value, and that the ring is opened and the secondary coil withdrawn. With most substances we find that the galvanometer deflection is precisely the same as if the current had been simply raised to its final value. It is not so with iron: the galvanometer deflection depends not alone upon the current at the moment of withdrawal, but on the current to which the ring has been previously subjected. We may then draw another curve (Fig. 2) representing the galvanometer deflections produced when the current has been raised to a high value and has been subsequently reduced to a value indicated by the abscissæ. This curve may be properly called a descending curve. In the case of ordinary bodies this curve is a straight line coincident with the straight line of the ascending curve, but for iron is a curve such as is represented in the drawing. You observe that this curve descends to nothing like zero when the current is reduced to zero; and that when the current is not only diminished to zero, but is reversed, the galvanometer deflection only becomes zero when the reversed current has a substantial value. This property possessed by magnetic bodies of retaining that which is impressed upon them by the primary current has been called by Prof. Ewing "hysteresis," or, as similar properties have been observed in quite other connections, "magnetic hysteresis." The name is a good one, and has been adopted. Broadly speaking, the induction as measured by the galvanometer deflection is independent of the time during which the successive currents have acted, and depends only upon their magnitude and order of succession. Some recent experiments of Prof. Ewing, however, seem to show a well-marked time effect. There are curious features in these experiments which require more elucidation.

It has been pointed out by Warburg, and subsequently by Ewing, that the area of curve 2 is a measure of the quantity of energy expended in changing the magnetism of the mass of iron from that produced by the current in one direction to that produced by the current in the opposite direction and back again. The energy expended with varying amplitude of magnetizing forces has been determined for iron, and also for large magnetizing forces for a considerable variety of samples of steel. Different sorts of iron and steel differ from each other very greatly in this respect. For example, the energy lost in a complete cycle of reversals in a sample of Whitworth's mild steel was about 10,000 ergs per cubic centimetre; in oil-

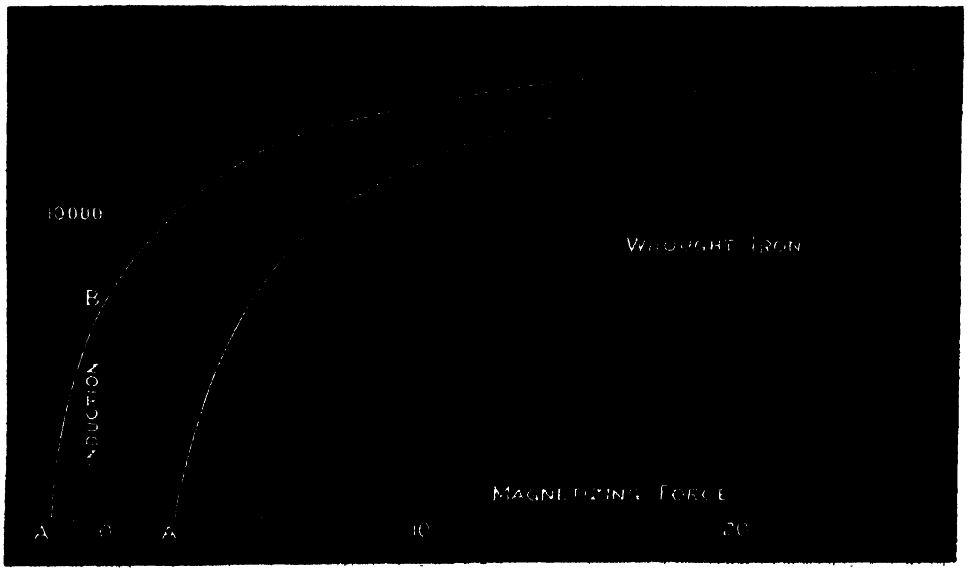

FIG. 2.

hardened hard steel it was near 100,000; and in tungsten steel it was near 200,000—a range of variation of 20 to 1. It is, of course, of the greatest possible importance to keep this quantity low in the case of armatures of dynamos, and in that of the cores of transformers. If the armature of a dynamo machine be made of good iron, the loss from hysteresis may easily be less than 1 per cent; if, however, to take an extreme case, it were made of tungsten steel, it would readily amount to 20 per cent. In the case of transformers and alternate-current dynamo machines, where the number of reversals per second is great, the loss of power by hysteresis of the iron, and the consequent heating, become very important. The loss of power by hysteresis increases more rapidly than does the induction. Hence it is not well in such machines to work the iron to anything like the same intensity of induction as is desirable in ordinary continuous current machines. The quantity O A, when measured in proper units, as already explained—that is to say, the reversed magnetic force, which just suffices to reduce the induction as measured by the kick on the galvanometer to nothing after the material has been submitted to a very great magnetizing force—is called the "coercive force," giving a definite meaning to a term which has long been used in a somewhat indefinite sense. The quantity is really the important one in judging the magnetism of short permanent magnets. The residual magnetism, O B, is then practically of no interest at all; the magnetic moment depends almost entirely upon the coercive force. The range of magnitude is somewhat greater than in the case of the energy dissipated in a complete reversal. For very soft iron the coercive force is 1·6 C.G.S. units; for tungsten steel, the most suitable material for magnets, it is 51 in the same units. A very good guess may be made of the amount of coercive force in a sample of iron or steel by the form of the ascending curve, determined as I described at first. This is readily seen by inspection of Fig. 3, which shows the curves in the cases of wrought iron, and steel containing 0·9 per cent. of carbon. With the wrought iron a rapid ascent of the ascending curve is made, when the magnetizing force is small and the coercive force is small; in the case of the hard steel the ascent of the curve is made with a larger magnetizing current, and the coercive force is large. There is one curious feature shown in the curve for hard steel which may, so far as I know, be observed in all magnetizable substances: the ascending curve twice cuts the descending curve, as at M and N. This peculiarity was, so far as I know, first observed by Prof. G. Wiedemann.

I have already called emphatic attention to the fact that magnetic substances are enormously magnetic, and that non-magnetic substances are hardly at all magnetic:

there is between the two classes no intermediate class. The magnetic property of iron is exceedingly easily destroyed. If iron be alloyed with 12 per cent. of manganese, the kick on the galvanometer which the material will give, if made into a ring, is only about 25 per cent. greater than is the case with the most completely non-magnetic material, instead of being some hundreds of times as great, as would be the case with iron. Further, with this manganese steel, the kick on the galvanometer is strictly proportional to the magnetizing current in the primary, and the material shows no sign of hysteresis. In short, all its properties would be fully accounted for if we supposed that manganese steel consisted of a perfectly non-magnetic material, with a small percentage of metallic iron mechanically admixed therewith. Thus the property of non-magnetizability of manganese steel is an excellent proof of the fact—which is also shown by the non-magnetic properties of most compounds of iron—that the property appertains to the molecule, and not to the atom; or, to put it in another way, suppose that we were to imagine manganese steel broken up into small particles, as these particles became smaller there would at length arrive a point at which the iron and the manganese would be entirely separated from each other: when this point is reached the particles of iron are non-magnetic. By the magnetic molecule of the substance we mean the smallest part which has all the magnetic properties of the mass. The magnetic molecule must be big enough to contain its proportion of manganese. In iron, then, we must have a collection of particles of such magnitude that it would be possible for the manganese to enter into each of them, to constitute an element of the magnet. Manganese is, so far as I know, a non-magnetic element. Smaller proportions of manganese reduce the magnetic property in a somewhat less degree, the reduction being greater as the quantity of manganese is greater. It appeared very possible that the non-magnetic property of manganese steel was due to the coercive force being very great—that, in fact, in all experiments we were still on that part of the magnetization curve below the rapid

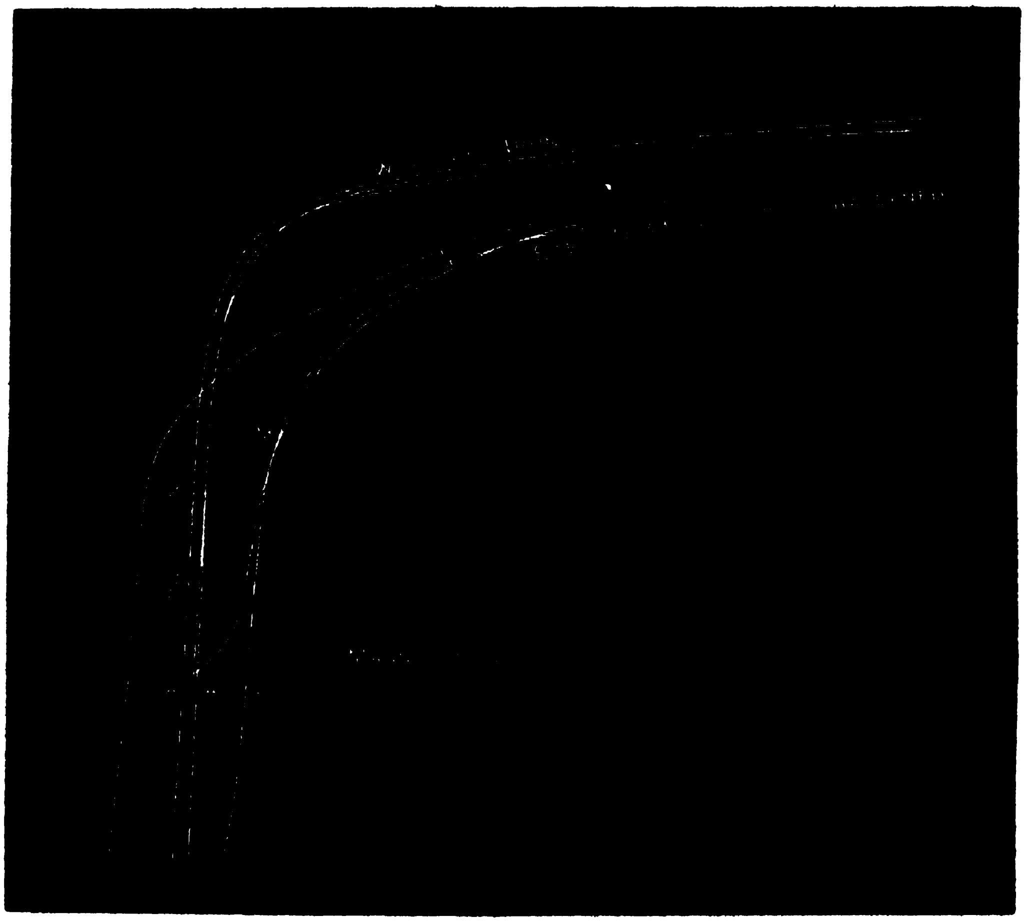

FIG. 3.

rise, and that if the steel were submitted to greater forces it would presently prove to be magnetic, like other kinds of steel. Prof. Ewing, however, has submitted manganese steel to very great forces indeed, and finds that its magnetism is always proportional to the magnetizing force.

No single body is known having the property of capacity for magnetism in a degree which is neither very great nor very small, but intermediate between the two extremes. We can, however, mix magnetic and non-magnetic substances to form bodies apparently intermediate. It is, therefore, interesting to consider what the properties might be of such a mixture. It depends quite as much on the way in which the magnetic part is arranged in the mass, as on its actual quantity. Suppose, for example, it is arranged as in Fig. 4—in threads or plates having a very long axis in the direction of the magnetizing force—we may at once determine the curve of magnetization of the mixture from that of the magnetic substance by dividing the induction for any given force in the ratio of the whole volume to the volume of magnetic substance. If, on the other hand, it is as in Fig. 5—with a very short axis in the direction of the force, and a long axis perpendicular thereto—we can equally construct the curve of magnetization. This is done in Fig. 6, which shows the curve when nine-tenths of the material is highly magnetic iron, arranged as in Fig. 5, whilst the other curve of the same figure is that when only one-tenth is magnetic, but arranged as in Fig. 4. You observe how very different is the character of the curve—a difference which is reduced by the much less proportion of magnetic material in the mixture in the one case than in the other. One peculiarity of these arrangements of the two materials in relation to each other is, that the resulting material is not isotropic; that is, its properties are not the same in all directions, but depend upon the direction of the magnetizing force in the material. Of course, this is not at all a probable arrangement, but it is instructive in showing the character of the

result as depending upon the construction of the material. Let us, however, consider the simplest isotropic arrangement; let us suppose that one material is in the form of spheres bedded in a matrix of the other: if the spheres are placed at random this is clearly an isotropic arrangement. The result is very different according as the matrix or the spheres are of the magnetic material. Suppose that the volume of the spheres is one-half of the whole volume. In Fig. 7 we have approximately the curve for iron, for a mixture of equal quantities of iron and a non-magnetic material; the spheres being non-magnetic and the matrix iron, and for a mixture, the

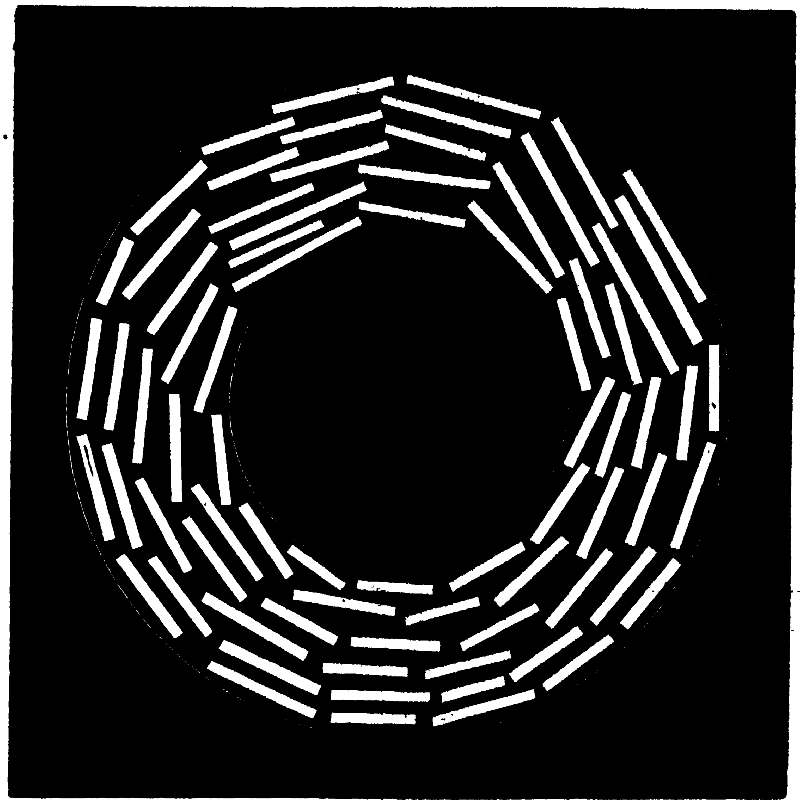

Fig. 4.

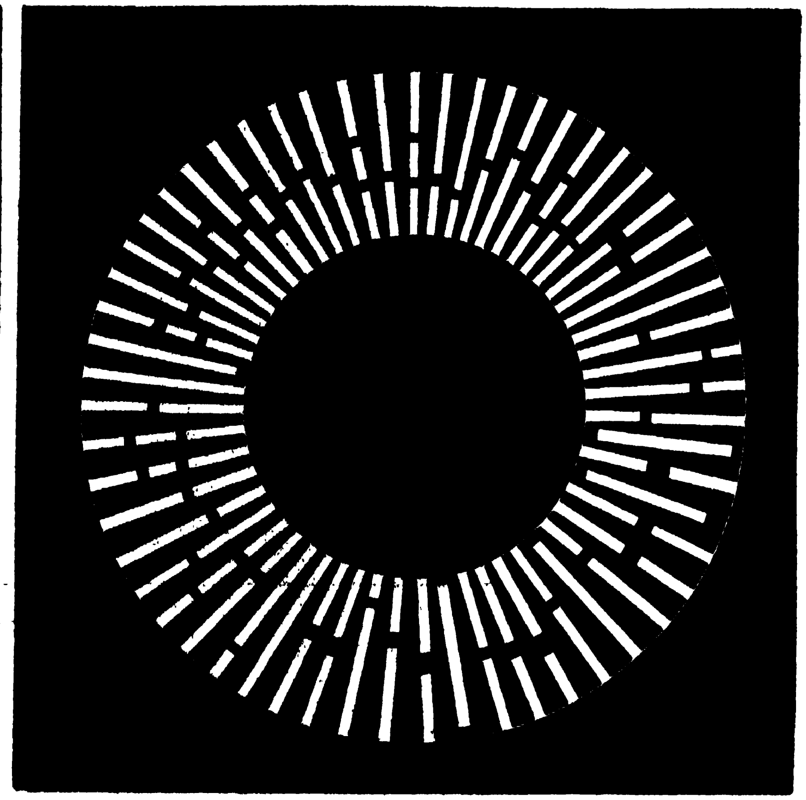

Fig. 5.

spheres being iron and the matrix non-magnetic. Observe the great difference. When the spheres are iron, the induction is near four times the force for all values of the force. When the matrix is iron, the induction is near two-fifths of the induction when the material is iron only.

In speaking of the properties of bodies which, like manganese steel, are slightly magnetic, it may be well here to enter a caution. But little that is instructive is to be learned by testing filings, or the like, with magnets, as these show but little difference between bodies which are slightly magnetic and those which are strongly

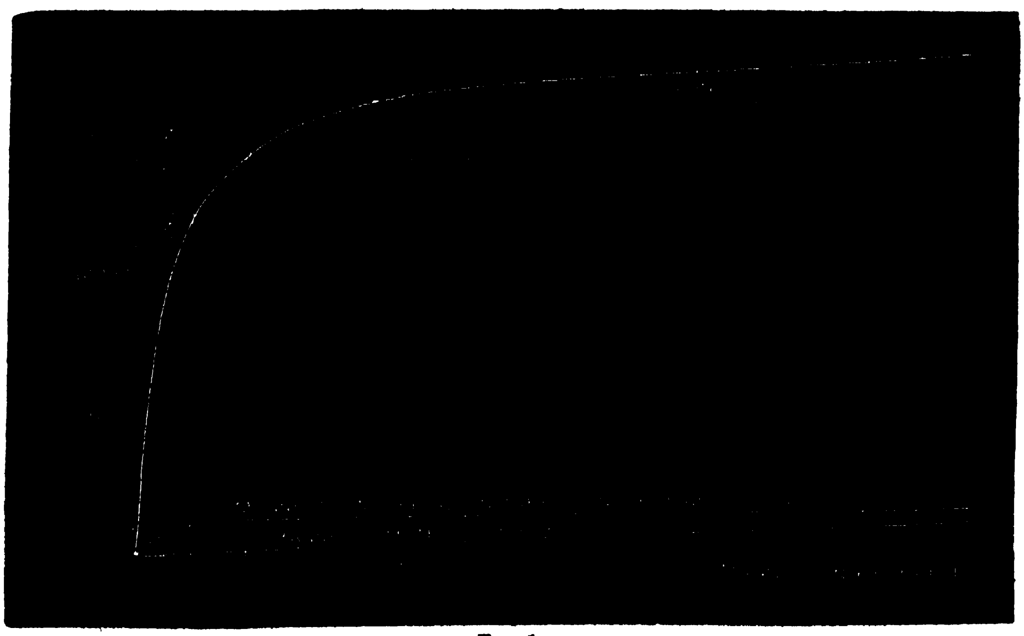

Fig. 6.

magnetic. Suppose the filings to be spheres; in the following table are given comparative values of the forces they would experience in terms of μ, if placed in a magnetic field of given value, μ having its ordinary signification—that is, being the ratio of the kick on the galvanometer when a ring is tried made of the material of the filing to the kick if t[illegible]ctly non-magnetic material:—

μ	Attraction.	
1	0	Non-magnetic body.
1·47	0·18	Manganese steel with 12 per cent.
3·6	1·2	Manganese steel with 9 per cent.
5	1·5	
10	2·1	
100	2·8	
1000	2·9?	

Now bodies in which μ is so small as 3·6 belong distinctly to the non-magnetic class; but the test with the magnet would very markedly distinguish them from manganese steel with 12 per cent of manganese. The distinction, however, between $\mu = 3·6$ and $\mu = 1000$ is comparatively small; whereas, under the conditions of experiment, μ is much more than 1000 for most bodies of which iron is the principal constituent.

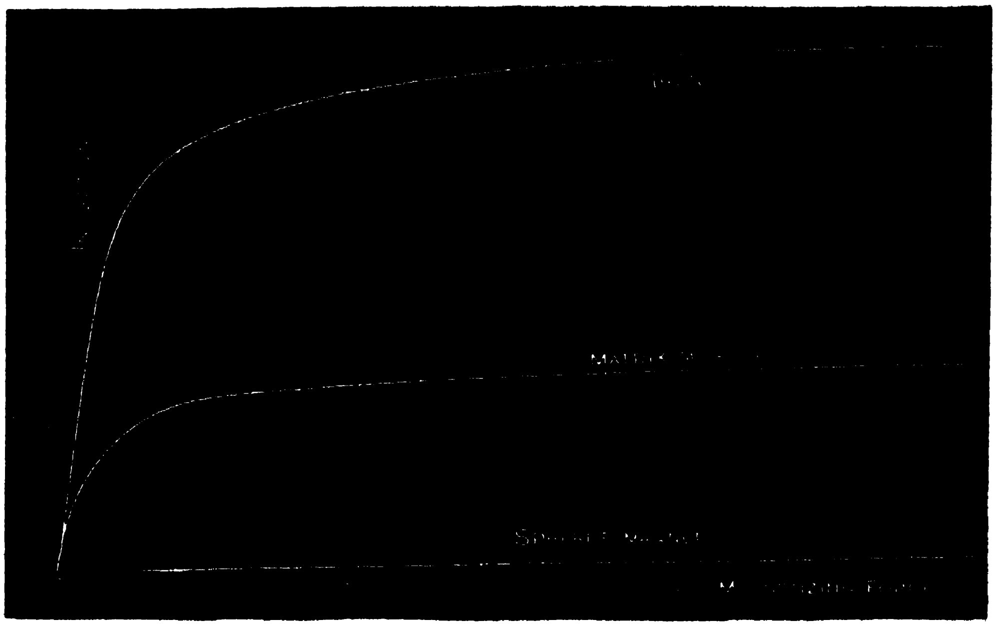

FIG. 7.

The effect of stress on the magnetic properties of iron and nickel have been studied by Sir W. Thomson. A fact interesting from a broad and general point of view is that the effects of stress are different in kind in the case of iron and nickel. In the case of iron, for small magnetizing forces in the direction of the tension, tension increases the magnetization; for large forces, diminishes it. In the case of nickel the effect is always to diminish the magnetization.

(*To be continued*)

LORENZO RESPIGHI.

DURING the last forty years the Eternal City has possessed two astronomical observatories. It was at the old building, connected with the Collegio Romano, that Scheiner collected the principal materials for his famous work on the sun, called from its dedication to Prince Orsini, the Duke of Bracciano, "Rosa Ursina"; and though it is with some justice that Delambre speaks disparagingly of its contents as compared with its bulk, the observations of the solar spots show with what care they were made, and they afford the first indication of the now familiar fact that their rotation varies in duration in different heliographical latitudes, though Scheiner's idea seems to have been that it was not the same in the two solar hemispheres. But it was not until 1787 that the present observatory of the Collegio Romano was commenced, nor until 1804 that the general interest felt in the great eclipse of February 11 in that year induced Pope Pius VII. to provide G. Calandrelli with the means of furnishing it with suitable instruments. Another astronomical phenomenon, the appearance of the great comet of 1843, led his son Ignazio Calandrelli, to wish to form a new observatory on the Capitoline Hill; but it was not until five years later that Pius IX. was able, in 1848, to provide him with the means for carrying out this design. Meanwhile Calandrelli continued his observations at Bologna, ably assisted by the subject of our notice.

Lorenzo Respighi was born at Cortemaggiore, in the province of Placentia, in 1824. His first studies were made at Parma, from which town he proceeded to the University of Bologna, where he obtained high honours in the departments of mathematics and philosophy in 1847. Nominated Professor of Optics and Astronomy in 1851, he subsequently succeeded Calandrelli as Director of the Observatory. On the retirement of the latter in 1865 (followed by his death in 1866) Respighi was appointed his successor. His earliest papers were on mechanical and optical subjects; but he will be best remembered by his subsequent labours on stellar spectra, on those of the solar corona and protuberances, and on the scintillation of the stars. In 1871 he went on an expedition to Poodocottah, in Hindustan, to observe the total eclipse of December 12 in that year; an account of the observations will be found in the eclipse (41st) volume of the Memoirs of the Royal Astronomical Society, of which Respighi was elected an Associate in 1872. He formed from his observations between 1875 and 1881 a catalogue of 2534 stars in the northern hemisphere from the first to the sixth magnitude, which was published in successive numbers of the Memoirs of the Lincean Academy.

His death took place after a long illness, aggravated by the recent epidemic, on December 10 last, and the Campidoglio Observatory has thus been deprived of its second director, who has so ably and energetically conducted its operations during nearly the last quarter of a century.

W. T. LYNN.

NOTES.

ON Saturday evening, at the Royal Institution, Prof. Max Müller delivered an address to inaugurate the establishment of a school for modern Oriental studies by the Imperial Institute in union with University College and King's College, London. The Prince of Wales presided, and among those present were many eminent persons, including some distinguished Orientals Prof. Müller presented with admirable force and clearness the need for a great English school for Oriental studies, and had much to tell his hearers as to work done in this direction in other countries. His account of the new Berlin seminary of

Oriental languages was particularly interesting. This institution has the following staff of professors and teachers:—One professor of Chinese; two teachers of Chinese, both natives—one for teaching North Chinese, the other South Chinese; one professor of Japanese, assisted by a native teacher; one professor of Arabic, assisted by two native teachers—one for Arabic as spoken in Egypt, the other for Arabic as spoken in Syria; one native teacher of Hindustani and Persian; one native teacher of Turkish; one teacher of Suaheli, an important language spoken on the East Coast of Africa, assisted by a native. Besides these special lectures, those given by the most eminent professors of Sanskrit, Arabic, Persian, and Chinese in the Universities of Berlin are open to the students of the Oriental seminary. The number of students amounts at present to 115. Of these, 56 are said to belong to the faculty of law, which must be taken to include all who aspire to any employment in the consular and colonial services. Fifteen belong to the faculties of philosophy, medicine, and physical science; four to the faculty of theology, who are probably intended for missionary work. Twenty-three are mentioned as engaged in mercantile pursuits, three are technical students, five officers in the army, and nine are returned as studying modern Greek and Spanish, languages not generally counted as Oriental, though, no doubt, of great usefulness in the East and in America. Prof. Müller succeeded in conveying a remarkably vivid impression of the fact that England, looking at the subject simply from the point of view of her own material interests, cannot afford to neglect the studies to which so much attention is devoted elsewhere. "England," he said, "cannot live an isolated life. She must be able to breathe, to grow, to expand, if she is to live at all. Her productive power is far too much for herself, too much even for Europe. She must have a wider field for her unceasing activity, and that field is the East, with its many races, its many markets, its many languages. To allow herself to be forestalled or to be ousted by more eloquent and persuasive competitors from those vast fields of commerce would be simple suicide. Our school, in claiming national support, appeals first of all to the instinct of self-preservation. It says to every manufacturing town in England, help us, and, in doing so, help thyself. Whenever the safety and honour of England are at stake we know what enormous sums Parliament is willing to vote for army and navy, for fortresses and harbours —sums larger than any other Parliament would venture to name. We want very little for our School of Oriental Languages, but we want at least as much as other countries devote to the same object. We want it for the very existence of England; for the vital condition of her existence is her commerce, and the best markets for that commerce lie in the East."

On Saturday, February 22, the Physikalisch-ökonomische Gesellschaft of Königsberg is to hold its centenary celebration. The proceedings will consist of a Festsitzung at 11 a.m., a visit to the Provinzial-Museum at 1, and a Festessen at 8 p.m.

Several courses of afternoon lectures which promise to be exceptionally interesting will be delivered during the present season at the Royal Institution. On January 21 Mr. G. J. Romanes, F.R.S., will begin a series of ten lectures, forming the third part of his course on "Before and After Darwin." This series will relate to the post-Darwinian period, and will include a discussion of Weismann's theory of heredity. Prof. Flower, F.R.S., will begin on January 25 a course of three lectures on the natural history of the horse, and of its extinct and existing allies. A course of four lectures on the early developments of the forms of instrumental music will be begun by Mr. F. Niecks on March 6.

The annual general meeting of the Institution of Mechanical Engineers will be held at 25 Great George Street, Westminster, on January 29, 30, and 31. The chair will be taken each evening by the President at 7.30 p.m. The following are the papers: on the compounding of locomotives burning petroleum refuse in Russia, by Thomas Urquhart; on the burning of colonial coal in the locomotives of the Cape Government railways, by Michael Stephens; on the mechanical appliances employed in the manufacture and storage of oxygen, by Kenneth S. Murray.

The annual general meeting of the Anthropological Institute of Great Britain and Ireland will take place on Tuesday, the 28th inst., at 8.30 p.m., Dr. John Beddoe, F.R.S., President, in the chair. The following will be the order of business:— Confirmation of the minutes, appointment of scrutineers of the ballot, Treasurer's financial statement, Report of Council for 1889, the Presidential Address, report of scrutineers, and election of Council for 1890.

During the last few years anthropological studies have excited a good deal of popular interest, and lately it occurred to the Council of the Anthropological Institute that it might be worth while for them to arrange for the preparation of a series of lectures presenting clearly the results of recent anthropological research. Accordingly a course on the following branches of the subject has been planned: physical anthropology; the geological history of man; prehistoric and non-historic dwellings, tombs, and ornaments; the development of the arts of life; social institutions; anthropometry. The Assistant-Secretary of the Institute is prepared to arrange for the delivery of these lectures at places within convenient distance of London.

The first volume of Prof. Thorpe's "Dictionary of Applied Chemistry" (Longmans) will be published in a few days. The work will consist of three volumes, and will treat specially of chemistry in its relations to the arts and manufactures. It will be uniform with the new edition of Watts's "Dictionary of Chemistry," edited by Muir and Morley.

M. Granel has been appointed Professor of Botany to the Faculty of Medicine at Montpellier.

On Monday the Khedive opened the new Museum at Ghizeh, whither the archæological treasures hitherto preserved at Boulak have been transferred.

The "tercentenary of the invention of the compound microscope" will be celebrated by a Universal Exhibition of Botany and Microscopy, to be held at Antwerp during the present year, under the auspices of M. Ch. de Bosschere, President, M. Ch. Van Geert, Secretary, and Dr. H. Van Heurck, Vice-President. It is proposed to organize an historical exhibition of microscopes and an exhibition of the instruments of all makers, and of accessory apparatus and photomicrography. At the conferences the following subjects will be discussed and illustrated:—The history of the microscope; the use of the microscope; the projecting microscope and photomicrography; the microscopical structure of plants; the microscopical structure of man and of animals; microbes; the adulteration of food-substances, &c. Communications are to be addressed to M. Ch. de Bosschere, Lierre, Belgium.

We regret to have to record the death of Mr. Daniel Adamson, well known from his connection with the iron and steel industries. He died on Monday at the age of 71. Mr. Adamson was President of the Iron and Steel Institute in 1887, and was a member of other mechanical and scientific associations.

Dr. F. Hauck, the eminent algologist, died at Trieste on December 21, 1889, at the early age of forty-four. He was the author of the volume on marine Algæ in the new edition of Rabenhorst's "Cryptogamic Flora of Germany."

The December number of the *American Geologist* contains an interesting paper, by William Upham, on the late Prof. Henry Carvill Lewis, who, it will be remembered, died at Manchester on July 21, 1888, a day or two after his arrival in this country from America. He became ill during the voyage,

and it seems that the immediate cause was the contamination of the water supply of Philadelphia, where he had been living, and where about a thousand cases of typhoid fever appeared at nearly the same time. Prof. Lewis was only in his thirty-fifth year. An excellent portrait of him accompanies Mr. Upham's paper.

AT the meeting of the University Experimental Science Association, Dublin, on December 13, Mr. J. Joly read a paper on a resonance method of measuring the constant of gravitation. A simple pendulum of small mass is hung in a tall glass tube, rendered vacuous. In close proximity two massive pendulums, one at either side, are maintained in a state of vibration for any desired period of time. The times of vibration of all these pendulums are alike. The observations consist in observing the amplitude, or the increase of amplitude, of the central pendulum, after a known number of vibrations executed by the exterior pendulums. Several modifications, carrying out the same principle, were suggested. It is proposed to test the method in the vaults of the physical laboratory.

THE Central Meteorological Observatory of Mexico, which is situated at 7489 feet above the sea, has published a summary of meteorological results for each month of twelve years ending 1888 (excepting January and February 1877). The coldest month is January, the mean temperature of which is 54°, and the warmest month is April, the mean temperature of which is 64°. The absolute maximum in the shade was 89°, and the minimum 28°·9. The wettest month is August, in which the mean rainfall is 5·4 inches, and the driest month is February, with an average of 0·4 inch. The greatest fall at one time was 2·5 inches. The prevalent direction of the wind is north-west.

THE *Essex County Chronicle* of January 10 says that on Tuesday, the 7th inst., two slight shocks of earthquake were noticed at Chelmsford. The first occurred at 12.30, when a low rumbling sound like thunder in the distance was heard, accompanied by a vibration of the ground and a rattling of the windows. The shock was observed in several parts of the town. The more pronounced shock was, however, at 1.25 p.m., when the rumbling, moaning sound was intensified, there being a heavy throbbing in the air like the pulsation of an engine. At many houses there was a violent shaking of the windows, and two cases are reported of things trembling on the tables. Some men working for Mr. Norrington heard the sound, took it to be the rumble of a heavy waggon, and went out to see it. Nothing was in sight. Several people recognized the shock as being similar to the forerunner of the 1884 earthquake, and rushed out of their houses. Mr. Arthur E. Brown, writing to us from Brentwood, says that the shocks were noticed there. They were attributed by the people in his house to the firing of guns at Woolwich. They rattled the doors violently.

A CORRESPONDENT writes that during the thunderstorm which prevailed over the greater part of Scotland early on Monday morning, January 6, a slight shock of earthquake was felt in a district of Perthshire. "This," he says, "is somewhat similar to what took place at Argyll on the evening of July 15 last year, and might lead one to suppose that atmospheric influence has something to do with the production of seismic disturbances."

AT a meeting of the Royal Botanic Society on Saturday, attention was called to a specimen of the double cocoanut, or *coco de mer*, now known to come from the Seychelles. For some hundreds of years these nuts have been occasionally found washed up by the sea, and their extraordinary appearance, large size, and mysterious origin have given rise to many stories of miraculous virtue in the cure of diseases. Some are even said to have been sold for their weight in gold. This specimen belonged to General Gordon, and was given by him to General Gerald Graham, by whom it has been presented to the Society.

THE Transactions of the Congrès pour l'Utilisation des Eaux fluviales, held last summer in Paris, have just been issued. The volume contains a great number of engravings.

A BOOK on the Congo State, by E. Dupont, the Director of the Natural History Museum of Brussels, has just been published. He presents the scientific results of his travels, devoting especial attention to geological questions.

MESSRS. GEORGE PHILIP AND SON have published the second issue of their valuable "Educational Annual." The work has been enlarged, revised, and to some extent rearranged; and it ought to be of great service to all who are for any reason especially interested in educational institutions.

MESSRS. PERKEN, SON, AND RAYMENT have produced a projecting optical lantern, which is likely to be of considerable service. When enlargements are required, a condenser of 10-inch diameter is available; but when a magic-lantern entertainment is to be provided, a condenser of 4-inch diameter can be substituted. The apparatus consists of a mahogany-body lantern with a long bellows-camera adjusted by the patent quick-action rack and pinion, and lighted by the refulgent three-wick lamp.

ON January 21, and the three following evenings, Dr. E. Symes Thomson will deliver, at Gresham College, a course of lectures on influenza or epidemic catarrh. In the first lecture he will present a historical sketch of the subject. The remaining lectures will be on influenza as it affects the lower animals, the causes and consequences of influenza, and diagnosis and management.

THE additions to the Zoological Society's Gardens during the past week include four Leopard Tortoises (*Testudo pardalis*), three Well-marked Tortoises (*Homopus signatus*), a Rufous Snake (*Ablabes rufulus*), six Gray's Frogs (*Rana grayi*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; two Spur-winged Geese (*Plectropterus gambensis*) from West Africa, presented by Mr. C. B. Mitford; six Red-bellied Waxbills (*Estrelda rubriventris*), five Crimson-eared Waxbills (*Estrelda phœnicotis*), seven Grenadier Waxbills (*Uræginthus grantinus*, 6 ♂ 1 ♀), three Paradise Whydah Birds (*Vidua paradisea*), three —— Weaver Birds (*Euplectes* ——) from Benguela, West Africa, presented by Mr. T. W. Bacon; a Bluish Finch (*Spermophila cærulescens* ♂) from Brazil, presented by Mrs. Mayne; a Green Turtle (*Chelone viridis*) from the West Indies, presented by Mrs. Harris; a Chattering Lory (*Lorius garrulus*) from Moluccas, presented by Captain Bason, P. and O. s.s. *Bombay*; three Yellow-winged Sugar Birds (*Cœrea cyanea*), two Yellow-fronted Tanagers (*Euphonia flavifrons*) from South America, deposited; four Tufted Umbres (*Scopus umbretta*) from Africa, a Geoffroy's Terrapin (*Hydraspis hilarii*) from the Argentine Republic, purchased; a Koala (*Phascolarctus cinereus* ♀) from Australia, two Indian Cobras (*Naia tripudians*), an Indian Python (*Python molurus*) from India, received in exchange.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m., January 16 = 5h. 45m. 8s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 1185	—	—	5 30 7	− 5 20
(2) 119 Tauri	4	Reddish-yellow.	5 25 46	+18 31
(3) σ Orionis	4	Whitish-yellow.	5 33 12	− 2 40
(4) γ Orionis	2	White.	5 19 12	+ 6 15
(5) 64 Schj.	8	Very red.	5 38 29	+24 22
(6) R Ceti	Var	Yellowish-red.	2 20 24	− 0 40
(7) U Ceti	Var.	Reddish.	2 28 26	−13 37

Remarks.

(1) This is described in Herschel's general catalogue as "a remarkable object, very large, round, with tail, much brighter in the middle." The spectrum has not yet been recorded, but it promises to be one of great interest, as the nebula is apparently one of the cometic ones. The meteoritic hypothesis suggests that these are produced by a condensed swarm moving at a high velocity through a sheet of meteorites at rest, or a swarm almost at rest surrounded by a moving sheet. In the former case the collision region would be behind the swarm, and would be spread out like a comet's tail, the angle of the fan and length of "tail" depending upon the velocity of the moving swarm. Observations for variations of spectrum between nucleus and tail will also be valuable.

(2) This is a typical example of stars of Group II. Observations similar to those suggested for 20 Leporis, U.A., last week, are required.

(3) Konkoly classes this with stars of the solar type. The usual differential observations, as to whether the star belongs to Group III. or to Group V., are required.

(4) In Gothard's list of star spectra this is described as Group IV. The usual observations are suggested.

(5) Dunér describes the spectrum of this star as Group VI., but his description is not complete. The characters of the different bands, especially of Band 6, require further observation. It may be remarked in connection with these stars of small magnitude, that the observations are by no means so difficult as in the case of small stars with spectra consisting of fine lines. The bands are broad and generally dark, so that the continuous spectrum is broken up into zones.

(6) This variable has a period of 167 days, and ranges in magnitude from about 8 at maximum to 13 at minimum. The spectrum is of the Group II. type, and, as in other variables of the same group, bright lines may appear at maximum. Dunér states that the bands are very wide and dark, but he does not state what bands are present. Maximum on January 18.

(7) The spectrum of this variable has not yet been recorded, but the colour indicates that it is probably either Group II. or Group VI. The period is 228 days, and the range from 7 at maximum to 10 at minimum. The maximum will occur on January 18.

A. FOWLER.

THE TEMPERATURE OF THE MOON.—Prof. Langley, by means of the bolometer, made some measurements of the heat from different parts of the eclipsed moon on the night of September 23, 1885 (*Phil. Mag.*, January, 1890). These measurements were made in connection with a much more extended study on the temperature of our satellite. The following particulars are given:—The diameter of the lunar image was 28·3 millimetres, and of this only a limited portion (0·08 of the whole) fell upon the bolometer. As the penumbra came on, the diminution of heat was marked, being measured by the bolometer even before the eye had detected any appearance of shadow. The heat continued to diminish rapidly with the progress of the immersion in the penumbra. At one hour before the middle of the total eclipse, the deflection in the umbra was 3·8 divisions. Fifty minutes after the middle of the eclipse, it had diminished to approximately 1·3 divisions, this being less than 1 per cent. of the heat from a similar portion of the uneclipsed moon. The rise of the temperature after the passage of the umbra was apparently nearly as rapid as the previous fall. The most important conclusion drawn by Prof. Langley from his researches is that the mean temperature of the sunlit lunar soil is most probably not greatly above zero Centigrade.

ON THE ORBIT OF STRUVE 228.—The *Monthly Notices* of the Royal Astronomical Society, December 1889, contains a note, communicated by Mr. J. E. Gore, on this binary star. Recent measures show that, since Struve discovered the star in 1829, it has described about 120° of its apparent orbit. The following provisional elements have been computed:—

Elements of Σ 228.

$P = 88·73$ years.	$\Omega = 84° 49'$
$T = 1906·03$	$\lambda = 51° 36'$
$e = 0·5311$	$a = 0''·98$
$i = 70° 59'$	$\mu = +4°·057$

According to this orbit, the distance between the components will gradually increase during the next few years up to a maximum of about 0''·55, and then diminish again as the companion approaches the periastron. The minimum distance will not be reached until the position angle is 180° (after the periastron passage), when the components will probably be separated by less than 0''·2. The binary lies a little preceding 62 Andromedæ, the position for 1890·0 being approximately—

R.A. 2h. 6m. 59s., Decl. + 46° 58'·4.

The magnitudes of the components are about 6·7 and 7·6.

ORBIT OF SWIFT'S COMET (V. 1880).—The orbit of this comet has been computed, by Gibbs's vector method, by Messrs. W. Beebe and A. W. Phillips (*Astr. Journ.*, Nos. 207, 208). This method is found to possess advantages over those of Gauss and Oppolzer. Below are given elements which have been computed from eight observations ranging from October 25, 1880, to January 7, 1881, and compared with these are the elements computed from three observations by Gibbs's method. Both are referred to the ecliptic and mean equinox of 1880·0:—

Eight observations.	Three observations.
$i = 5° 23' 3''·8$	$i = 5° 22' 2''·03$
$\pi - \Omega = 106 13 4·1$	$\pi - \Omega = 106 13 19·17$
$\Omega = 296 42 55·1$	$\Omega = 296 52 2·09$
$\log e = 9·8163726$	$\log e = 9·8146985$
$\log a = 0·4905937$	$\log a = 0·4873065$
T = 1880 Nov. 7·786610	T = 1880 Nov. 7·782810
Periodic time = 1988·33 days.	Periodic time = 1965·88 days.

ON THE VARIABILITY OF R VULPECULÆ.—Schönfeld, from a discussion of the observations from 1859 to 1874, found that a uniform period left systematic deviations outstanding which exceeded seven or eight times the uncertainty of the single maxima, but that a quadratic term, corresponding to a shortening of 0·12 days from epoch to epoch, brought them within the range of the probable errors. The divergence from observation, however, soon began, and rapidly widened, until in 1885 it amounted to 106·5 days. Mr. Chandler (*Astr. Journ.*, No. 208) gives a table showing the maxima and minima observed since 1807, with the deviations from the elements of his catalogue. It is seen that, whereas the difference between the observed and the calculated maxima and minima, using Schönfeld's elements, are very considerable, the elements given by the author differed from those observed only in a very slight degree.

ON THE ROTATION OF MERCURY.—Nearly a century has elapsed since Schröter published his first observation of the physical aspect of Mercury, and assigned to the planet a period of rotation; but it has been left to that perspicacious observer, Signor Schiaparelli, to demonstrate the fact by a series of remarkable observations given by him in *Astronomische Nachrichten*, No. 2944. The observations extend from 1882 to the end of last year. As many as 150 drawings have been made of the markings upon the planet with respect to the best positions for observation. It is noted that one of the finest drawings was made on August 11, 1882, when Mercury was only 3° 2' from the sun's limb. The markings that are visible on Mercury when observed at the same hour on consecutive days are identical in their aspect, and this being so, three hypotheses have been propounded (*Astr. Nach.*, 2479) regarding the rotation of the planet, viz.

That (1) the time of rotation is about 24 hours.

(2) The planet makes two or more rotations in the same interval.

(3) The time of rotation is so slow as to be inappreciable when observing the markings during a few days.

Schröter decided in favour of the first hypothesis, and Bessel, from a discussion of this observer's data, determined the time of rotation to be 24h. 0m. 52·97s. Schiaparelli's observations support the last of these hypotheses, and are opposed to the rotation period determined by Schröter.

Following a series of dark markings, shown in the figure which accompanies the article, it was found that—

Mercury revolves round the sun in the same manner that the moon revolves round the earth, always presenting to it the same hemisphere; hence, since the planet's periodic time is 87·9693 days, this must be the time of rotation on its axis.

The dark markings observed appear extremely faint, and are not easily recognized. On good occasions the colour may be seen to be reddish-brown, and always differs from the general colour of the planet's disk, which is a bright rose changing to copper.

This most interesting and important communication from Milan Observatory must be read in detail in order that it may be appreciated.

ON CERTAIN APPROXIMATE FORMULÆ FOR CALCULATING THE TRAJECTORIES OF SHOT.

In the postscript to a paper by Mr. W. D. Niven, "On the Calculation of the Trajectories of Shot," which is published in the Proceedings of the Royal Society, vol. xxvi. pp. 268–287, I have given, without demonstration, some convenient and not inelegant formulæ applicable to a limited arc of a trajectory when the resistance is supposed to vary as the nth power of the velocity.

In these formulæ, the angle between the chord of the arc and the tangent at any point is supposed to be always small. The index n is not restricted to integral values, but may take any value whatever.

As the proof of these formulæ is not altogether obvious, and a similar method of treatment may be found useful in other problems, I think it may not be unacceptable to your readers if I show here how the formulæ may be demonstrated.

Analysis.

Investigation of formulæ applicable to a small arc of a trajectory, when the resistance varies as the nth power of the velocity.

Let x and y denote the horizontal and vertical co-ordinates at time t, u the horizontal velocity, and ϕ the angle which the direction of motion makes with the horizon at the same time.

Hence the velocity at time t is $u \sec \phi$, and we may denote the resistance by $ku^n(\sec\phi)^n$, where k is constant throughout the small arc in question.

Also let p and q denote the values of u at the beginning and end of the arc, α and β the corresponding values of ϕ, g the force of gravity, T the time taken to describe the arc, X and Y the corresponding total horizontal and vertical motion.

Making ϕ the independent variable, the fundamental formulæ are—

$$(1)\quad \frac{du}{d\phi} = \frac{ku^{n+1}}{g}(\sec\phi)^{n+1};$$

$$(2)\quad \frac{dx}{d\phi} = -\frac{u^2}{g}(\sec\phi)^2;$$

$$(3)\quad \frac{dy}{d\phi} = -\frac{u^2}{g}(\sec\phi)^2\tan\phi;$$

$$(4)\quad \frac{dt}{d\phi} = -\frac{u}{g}(\sec\phi)^2.$$

From the first of these equations—

$$\frac{1}{u^{n+1}}\frac{du}{d\phi} = \frac{k}{g}(\sec\phi)^{n+1};$$

and therefore, by integration between the limits $\phi = \alpha$ and $\phi = \beta$,

$$\frac{1}{q^n} - \frac{1}{p^n} = \frac{kn}{g}\int_\beta^\alpha(\sec\phi)^{n+1}d\phi.$$

Also, we have—

$$\text{X} = \frac{1}{g}\int_\beta^\alpha u^2(\sec\phi)^2 d\phi;$$

$$\text{Y} = \frac{1}{g}\int_\beta^\alpha u^2(\sec\phi)^2\tan\phi\, d\phi;$$

and

$$\text{T} = \frac{1}{g}\int_\beta^\alpha u(\sec\phi)^2 d\phi;$$

and we wish to compare the two former of these definite integrals with the following known one, viz. :—

$$\frac{1}{q^{n-2}} - \frac{1}{p^{n-2}} = (n-2)\int_\beta^\alpha\frac{1}{u^{n-1}}\frac{du}{d\phi}d\phi = \frac{k(n-2)}{g}\int_\beta^\alpha u^2(\sec\phi)^{n+1}d\phi;$$

and the last with—

$$\frac{1}{q^{n-1}} - \frac{1}{p^{n-1}} = (n-1)\int_\beta^\alpha\frac{1}{u^n}\frac{du}{d\phi}d\phi = \frac{k(n-1)}{g}\int_\beta^\alpha u(\sec\phi)^{n+1}d\phi.$$

This may be done by means of the following lemma, which follows immediately from Taylor's theorem :—

Lemma.

If F(ϕ) be any function either of ϕ only, or of ϕ and u, where u is a function of ϕ given by the above differential equation (1), and if α and β be the limiting values of ϕ in the integral and $\gamma = \frac{1}{2}(\alpha+\beta)$, then, putting for a moment $\phi = \gamma + \omega$,

$$\int_\beta^\alpha \text{F}(\phi)d\phi = \int_{-\frac{1}{2}(\alpha-\beta)}^{\frac{1}{2}(\alpha-\beta)}\text{F}(\gamma+\omega)d\omega = \int_{-\frac{1}{2}(\alpha-\beta)}^{\frac{1}{2}(\alpha-\beta)}\left\{\text{F}(\gamma) + \text{F}'(\gamma)\omega + \text{F}''(\gamma)\frac{\omega^2}{2} + \text{F}'''(\gamma)\frac{\omega^3}{6} + \text{F}''''(\gamma)\frac{\omega^4}{24} + \&\text{c.}\right\}d\omega$$

$$= (\alpha-\beta)\left\{\text{F}(\gamma) + \frac{1}{24}(\alpha-\beta)^2\text{F}''(\gamma) + \frac{1}{1920}(\alpha-\beta)^4\text{F}''''(\gamma) + \&\text{c.}\right\}$$

where $\text{F}'(\phi) = \frac{d\text{F}(\phi)}{d\phi}$, $\text{F}''(\phi) = \frac{d^2\text{F}(\phi)}{d\phi^2}$, &c., and F($\gamma$), F′($\gamma$), F″($\gamma$), &c., are what F($\phi$), F′($\phi$), F″($\phi$), &c., become when γ is substituted for ϕ, and the corresponding value of u (u_0 suppose) is put for u.

In what follows, the last of the terms above written, which is of the 5th order in $(\alpha-\beta)$, is neglected, together with all terms of the same order of small quantities.

All the definite integrals with which we are here concerned are included in the two forms

$$\int_\beta^\alpha u^l(\sec\phi)^m d\phi, \text{ and } \int_\beta^\alpha u^l(\sec\phi)^m\tan\phi\, d\phi.$$

In the first place, we will apply the above formula to the case in which F(ϕ) is a function of ϕ only, viz. when $\text{F}(\phi) = (\sec\phi)^{n+1}$.

Hence

$$\text{F}'(\phi) = (n+1)(\sec\phi)^{n+1}\tan\phi;$$

$$\text{F}''(\phi) = (n+1)[(n+1)(\sec\phi)^{n+1}(\tan\phi)^2 + (\sec\phi)^{n+3}]$$

$$= (n+1)[\overline{n+2}(\sec\phi)^{n+3} - \overline{n+1}(\sec\phi)^{n+1}]$$

and therefore,

$$\int_\beta^\alpha(\sec\phi)^{n+1}d\phi = (\alpha-\beta)(\sec\gamma)^{n+1}\left\{1 + \frac{n+1}{24}(\alpha-\beta)^2[\overline{n+2}(\sec\gamma)^2 - \overline{n+1}]\right\}, \text{ to the 4th order inclusive.}$$

Hence

$$\frac{1}{q^n} - \frac{1}{p^n} = \frac{kn}{g}(\alpha-\beta)(\sec\gamma)^{n+1}\left\{1 + \frac{n+1}{24}(\alpha-\beta)^2[\overline{n+2}(\sec\gamma)^2 - \overline{n+1}]\right\},$$

which gives q when p is known.

In the next place, let $\text{F}(\phi) = u^l(\sec\phi)^m$.

Hence

$$\text{F}'(\phi) = \frac{d\text{F}\phi}{d\phi} = lu^{l-1}\frac{du}{d\phi}(\sec\phi)^m + mu^l(\sec\phi)^m\tan\phi$$

$$= \text{F}(\phi)\left[\frac{l}{u}\frac{du}{d\phi} + m\tan\phi\right],$$

or

$$\text{F}'(\phi) = \text{F}(\phi)\left[\frac{kl}{g}u^n(\sec\phi)^{n+1} + m\tan\phi\right];$$

and $F''(\phi) = F'(\phi)\left[\frac{kl}{g}u^n(\sec\phi)^{n+1} + m\tan\phi\right] + F(\phi)\left[\frac{kln}{g}u^{n-1}\frac{du}{d\phi}(\sec\phi)^{n+1} + \frac{kl}{g}(n+1)u^n(\sec\phi)^{n+1}\tan\phi + m(\sec\phi)^2\right]$,
or

$$F''(\phi) = F(\phi)\left[\frac{k^2l^2}{g^2}u^{2n}(\sec\phi)^{2n+2} + 2\frac{klm}{g}u^n(\sec\phi)^{n+1}\tan\phi + m^2(\sec\phi)^2 - m^2\right]$$
$$+ F(\phi)\left[\frac{k^2ln}{g^2}u^{2n}(\sec\phi)^{2n+2} + \frac{kl}{g}(n+1)u^n(\sec\phi)^{n+1}\tan\phi + m(\sec\phi)^2\right]$$
$$= F(\phi)\left\{\frac{k^2l}{g^2}(l+n)u^{2n}(\sec\phi)^{2n+2} + \frac{kl}{g}(2m+n+1)u^n(\sec\phi)^{n+1}\tan\phi + m(m+1)(\sec\phi)^2 - m^2\right\}.$$

Since

$$\frac{du}{d\phi} = \frac{k}{g}u^{n+1}(\sec\phi)^{n+1},$$

this last expression may be put under the form—

$$F''(\phi) = F(\phi)\left\{l(l+n)\left(\frac{du}{ud\phi}\right)^2 + l(2m+n+1)\left(\frac{du}{ud\phi}\right)\tan\phi + m(m+1)(\sec\phi)^2 - m^2\right\}.$$

Hence, by the above lemma,

$$\int_\beta^\alpha u^l\sec\phi^m d\phi = (\alpha-\beta)F(\gamma)\left\{1 + \tfrac{1}{24}(\alpha-\beta)^2\left[l(l+n)\left(\frac{du}{ud\phi}\right)_0^2 + l(2m+n+1)\left(\frac{du}{ud\phi}\right)_0\tan\gamma + m(m+1)(\sec\gamma)^2 - m^2\right]\right\}$$
$$= (\alpha-\beta)\,u_0^l(\sec\gamma)^m\left\{1 + \tfrac{1}{24}(\alpha-\beta)^2(\text{as before})\right\}$$

where $\left(\frac{du}{ud\phi}\right)_0$ denotes what $\frac{du}{ud\phi}$ becomes when $\omega = 0$, or when γ is substituted for ϕ, and u_0 for u, that is—

$$\left(\frac{du}{ud\phi}\right)_0 = \frac{k}{g}u_0^n(\sec\gamma)^{n+1}.$$

The factor u_0^l may be eliminated from this expression, and the expression itself simplified, by means of the formula—

$$\frac{1}{q^{n-l}} - \frac{1}{p^{n-l}} = (n-l)\int_\beta^\alpha\frac{1}{u^{n-l+1}}\frac{du}{d\phi}d\phi = \frac{k(n-l)}{g}\int_\beta^\alpha u^l(\sec\phi)^{n+1}d\phi,$$

for, putting $m = n+1$ in the above expression, we have—

$$\int_\beta^\alpha u^l(\sec\phi)^{n+1}d\phi = (\alpha-\beta)u_0^l(\sec\gamma)^{n+1}\left\{1 + \tfrac{1}{24}(\alpha-\beta)^2\left[l(l+n)\left(\frac{du}{ud\phi}\right)_0^2 + 3l(n+1)\left(\frac{du}{ud\phi}\right)_0\tan\gamma + \overline{n+1}\;\overline{n+2}\,(\sec\gamma)^2 - (n+1)^2\right]\right\}.$$

Hence

$$\int_\beta^\alpha u^l(\sec\phi)^m d\phi \div \int_\beta^\alpha u^l(\sec\phi)^{n+1}d\phi,\ \text{ or } \int_\beta^\alpha u^l(\sec\phi)^m d\phi \div \frac{g}{k(n-l)}\left(\frac{1}{q^{n-l}} - \frac{1}{p^{n-l}}\right)$$
$$= (\sec\gamma)^{m-n-1}\left\{1 + \tfrac{1}{24}(\alpha-\beta)^2\left[2l(m-n-1)\left(\frac{du}{ud\phi}\right)_0\tan\gamma + \overline{m-n-1}\;\overline{m+n+2}\,(\sec\gamma)^2 - \overline{m-n-1}\;\overline{m+n+1}\right]\right\}.$$

It will be noticed that the term involving $\left(\frac{du}{ud\phi}\right)_0^2$ has disappeared by this division.

Now make $m = 2$, and this formula becomes—

$$\int_\beta^\alpha u^l(\sec\phi)^2 d\phi = \frac{g}{k(n-l)}\left(\frac{1}{q^{n-l}} - \frac{1}{p^{n-l}}\right)(\cos\gamma)^{n-1}\left\{1 - \tfrac{1}{24}(\alpha-\beta)^2\left[2l(n-1)\left(\frac{du}{ud\phi}\right)_0\tan\gamma + \overline{n-1}\;\overline{n+4}\,(\sec\gamma)^2 - \overline{n-1}\;\overline{n+3}\right]\right\}.$$

Divide throughout by g, and put $l = 2$, then, from before,

$$X = \frac{1}{k(n-2)}\left(\frac{1}{q^{n-2}} - \frac{1}{p^{n-2}}\right)(\cos\gamma)^{n-1}\left\{1 - \frac{n-1}{24}(\alpha-\beta)^2\left[4\left(\frac{du}{ud\phi}\right)_0\tan\gamma + (n+4)(\sec\gamma)^2 - \overline{n+3}\right]\right\}.$$

Similarly, divide throughout by g, and put $l = 1$, then—

$$T = \frac{1}{k(n-1)}\left(\frac{1}{q^{n-1}} - \frac{1}{p^{n-1}}\right)(\cos\gamma)^{n-1}\left\{1 - \frac{n-1}{24}(\alpha-\beta)^2\left[2\left(\frac{du}{ud\phi}\right)_0\tan\gamma + (n+4)(\sec\gamma)^2 - \overline{n+3}\right]\right\}.$$

Lastly, let

$$F(\phi) = u^l(\sec\phi)^m\tan\phi = f(\phi)\tan\phi \text{ suppose,}$$

so that

$$f(\phi) = u^l(\sec\phi)^m;$$

then

$$F'(\phi) = f'(\phi)\tan\phi + f(\phi)(\sec\phi)^2,$$

and

$$F''(\phi) = f''(\phi)\tan\phi + 2f'(\phi)(\sec\phi)^2 + 2f(\phi)(\sec\phi)^2\tan\phi.$$

Hence

$$\int_\beta^\alpha F(\phi)d\phi = (\alpha-\beta)\{F(\gamma) + \tfrac{1}{24}(\alpha-\beta)^2F''(\gamma)\}\text{ approximately,}$$
$$= (\alpha-\beta)\left\{f(\gamma)\tan\gamma + \tfrac{1}{24}(\alpha-\beta)^2[f''(\gamma)\tan\gamma + 2f'(\gamma)(\sec\gamma)^2 + 2f(\gamma)(\sec\gamma)^2\tan\gamma]\right\};$$

also

$$\int_\beta^\alpha f(\phi)d\phi = (\alpha-\beta)\{f(\gamma) + \tfrac{1}{24}(\alpha-\beta)^2f''(\gamma)\}\text{ approximately;}$$

and therefore

$$\int_\beta^\alpha F(\phi)d\phi \div \int_\beta^\alpha f(\phi)d\phi = \tan\gamma + \tfrac{1}{12}(\alpha-\beta)^2\left[\frac{f'(\gamma)}{f(\gamma)}(\sec\gamma)^2 + (\sec\gamma)^2\tan\gamma\right];$$

in which the term involving $f''(\gamma)$ has disappeared.

Now, since $f(\phi) = u^l(\sec\phi)^m$, we have, as before

$$f'(\phi) = f(\phi)\left[l\left(\frac{du}{ud\phi}\right) + m\tan\phi\right];$$

and therefore—

$$\frac{f'(\gamma)}{f(\gamma)} = l\left(\frac{du}{ud\phi}\right)_0 + m\tan\gamma.$$

Hence—

$$\int_\beta^\alpha F(\phi)d\phi \div \int_\beta^\alpha f(\phi)d\phi = \tan\gamma + \tfrac{1}{12}(\alpha-\beta)^2(\sec\gamma)^2\left[l\left(\frac{du}{ud\phi}\right)_0 + \overline{m+1}\tan\gamma\right];$$

and in the particular case where $l = 2$, and $m = 2$, we have—

$$\frac{Y}{X} = \tan\gamma + \tfrac{1}{12}(\alpha-\beta)^2(\sec\gamma)^2\left[2\left(\frac{du}{ud\phi}\right)_0 + 3\tan\gamma\right]$$

$$= \tan\left\{\gamma + \tfrac{1}{12}(\alpha-\beta)^2\left[2\left(\frac{du}{ud\phi}\right)_0 + 3\tan\gamma\right]\right\}.$$

Hence the angle which the chord of the arc makes with the axis of x is—

$$\gamma + \tfrac{1}{12}(\alpha-\beta)^2\left[2\left(\frac{du}{ud\phi}\right)_0 + 3\tan\gamma\right] = \bar{\gamma}, \text{ suppose.}$$

Multiplying by the value of X found above, we have—

$$Y = \frac{1}{k(n-2)}\left(\frac{1}{q^{n-2}} - \frac{1}{p^{n-2}}\right)(\cos\gamma)^{n-1}\left\{\tan\gamma - \tfrac{1}{24}(\alpha-\beta)^2\left\{\left(\frac{du}{ud\phi}\right)_0\left[4\overline{n-1}(\tan\gamma)^2 - 4(\sec\gamma)^2\right] + \tan\gamma\left[\overline{n-1}\,\overline{n+4}(\sec\gamma)^2 - 6(\sec\gamma)^2 - \overline{n-1}\,\overline{n+3}\right]\right\}\right\};$$

or

$$Y = \frac{1}{k(n-2)}\left(\frac{1}{q^{n-2}} - \frac{1}{p^{n-2}}\right)(\cos\gamma)^{n-1}\left\{\tan\gamma - \tfrac{1}{24}(\alpha-\beta)^2\left\{\left(\frac{du}{ud\phi}\right)_0\left[4\overline{n-2}(\sec\gamma)^2 - 4\overline{n-1}\right] + \tan\gamma\left[\overline{n-2}\,\overline{n+5}(\sec\gamma)^2 - \overline{n-1}\,\overline{n+3}\right]\right\}\right\}.$$

Considering $\frac{1}{q^{n-2}} - \frac{1}{p^{n-2}}$, $\frac{1}{q^{n-1}} - \frac{1}{p^{n-1}}$, and $\alpha - \beta$ to be small quantities of the first order, the above expressions for $\frac{1}{q^n} - \frac{1}{p^n}$, X, Y, and T are true to the fourth order.

The quantity $\left(\frac{du}{ud\phi}\right)_0$ which occurs as a factor in some of the terms of the third order may be put under a very convenient form in the following manner.

We have, by Taylor's theorem,

$$u = (u_0) + \left(\frac{du}{d\phi}\right)_0\omega + \left(\frac{d^2u}{d\phi^2}\right)_0\frac{\omega^2}{2} + \&c.$$

In this make $\omega = \frac{1}{2}(\alpha-\beta)$ and $-\frac{1}{2}(\alpha-\beta)$ successively; therefore

$$p = u_0 + \tfrac{1}{2}(\alpha-\beta)\left(\frac{du}{d\phi}\right)_0 + \tfrac{1}{8}(\alpha-\beta)^2\left(\frac{d^2u}{d\phi^2}\right)_0 + \&c.,$$

and

$$q = u_0 - \tfrac{1}{2}(\alpha-\beta)\left(\frac{du}{d\phi}\right)_0 + \tfrac{1}{8}(\alpha-\beta)^2\left(\frac{d^2u}{d\phi^2}\right)_0 - \&c.$$

Hence we have to the first order of small quantities—

$$\frac{p-q}{\alpha-\beta} = \left(\frac{du}{d\phi}\right)_0,$$

and

$$\tfrac{1}{2}(p+q) = u_0;$$

and therefore

$$\left(\frac{du}{ud\phi}\right)_0 = \frac{2(p-q)}{(p+q)(\alpha-\beta)} \text{ to the first order.}$$

Making this substitution for $\left(\frac{du}{ud\phi}\right)_0$ the expressions for X, Y, and T become—

$$X = \frac{1}{k(n-2)}\left(\frac{1}{q^{n-2}} - \frac{1}{p^{n-2}}\right)(\cos\gamma)^{n-1}\left\{1 - \frac{n-1}{3}\cdot\frac{p-q}{p+q}(\alpha-\beta)\tan\gamma - \frac{n-1}{24}(\alpha-\beta)^2\left[\overline{n+4}(\sec\gamma)^2 - \overline{n+3}\right]\right\};$$

$$Y = \frac{1}{k(n-2)}\left(\frac{1}{q^{n-2}} - \frac{1}{p^{n-2}}\right)(\cos\gamma)^{n-1}\left\{\tan\gamma - \tfrac{1}{3}\cdot\frac{p-q}{p+q}(\alpha-\beta)\left[\overline{n-2}(\sec\gamma)^2 - \overline{n-1}\right] - \tfrac{1}{24}(\alpha-\beta)^2\tan\gamma\left[\overline{n-2}\,\overline{n+5}(\sec\gamma)^2 - \overline{n-1}\,\overline{n+3}\right]\right\};$$

$$T = \frac{1}{k(n-1)}\left(\frac{1}{q^{n-1}} - \frac{1}{p^{n-1}}\right)(\cos\gamma)^{n-1}\left\{1 - \frac{n-1}{6}\frac{p-q}{p+q}(\alpha-\beta)\tan\gamma - \frac{n-1}{24}(\alpha-\beta)^2\left[\overline{n+4}(\sec\gamma)^2 - \overline{n+3}\right]\right\};$$

and these values are still true to the fourth order, considering $\frac{p-q}{p+q}$ and $\alpha-\beta$ to be small quantities of the first order as before.

The angle which the chord of the arc makes with the axis of x becomes, in like manner—

$$\bar{\gamma} = \gamma + \tfrac{1}{3}\frac{p-q}{p+q}(\alpha-\beta) + \tfrac{1}{4}(\alpha-\beta)^2\tan\gamma,$$

which is true to the third order.

The above expressions for X and Y may be transformed by introducing this angle $\bar{\gamma}$ into them instead of γ, thus—

$$(\cos\bar{\gamma})^{n-1} = (\cos\gamma)^{n-1} - (n-1)(\cos\gamma)^{n-2}\sin\gamma\left[\tfrac{1}{3}\frac{p-q}{p+q}(\alpha-\beta) + \tfrac{1}{4}(\alpha-\beta)^2\tan\gamma\right]$$

$$= (\cos\gamma)^{n-1}\left\{1 - \frac{n-1}{3}\frac{p-q}{p+q}(\alpha-\beta)\tan\gamma - \frac{n-1}{4}(\alpha-\beta)^2(\tan\gamma)^2\right\}.$$

Hence we find—

$$X = \frac{1}{k(n-2)}\left(\frac{1}{q^{n-2}} - \frac{1}{p^{n-2}}\right)(\cos\bar{\gamma})^{n-1}\left\{1 - \frac{n-1}{24}(\alpha-\beta)^2[\overline{n-2}(\sec\gamma)^2 - \overline{n-3}]\right\},$$

and

$$Y = X\tan\bar{\gamma} = \frac{1}{k(n-2)}\left(\frac{1}{q^{n-2}} - \frac{1}{p^{n-2}}\right)(\cos\bar{\gamma})^{n-2}\sin\bar{\gamma}\left\{1 - \frac{n-1}{24}(\alpha-\beta)^2[\overline{n-2}(\sec\gamma)^2 - \overline{n-3}]\right\};$$

or

$$X = \frac{1}{k(n-2)}\left(\frac{1}{q^{n-2}} - \frac{1}{p^{n-2}}\right)(\cos\bar{\gamma})^{n-1}Q;$$

$$Y = \frac{1}{k(n-2)}\left(\frac{1}{q^{n-2}} - \frac{1}{p^{n-2}}\right)(\cos\bar{\gamma})^{n-2}\sin\bar{\gamma}\,Q;$$

Q being $= 1 - \frac{n-1}{24}(\alpha-\beta)^2[\overline{n-2}(\sec\gamma)^2 - \overline{n-3}]$.

Similarly, if

$$\bar{\gamma}' = \gamma + \tfrac{1}{6}\frac{p-q}{p+q}(\alpha-\beta) + \tfrac{1}{4}(\alpha-\beta)^2\tan\gamma,$$

we have

$$(\cos\bar{\gamma}')^{n-1} = (\cos\gamma)^{n-1} - (n-1)(\cos\gamma)^{n-2}\sin\gamma\left[\tfrac{1}{6}\frac{p-q}{p+q}(\alpha-\beta) + \tfrac{1}{4}(\alpha-\beta)^2\tan\gamma\right];$$

$$= (\cos\gamma)^{n-1}\left\{1 - \frac{n-1}{6}\frac{p-q}{p+q}(\alpha-\beta)\tan\gamma - \frac{n-1}{4}(\alpha-\beta)^2(\tan\gamma)^2\right\};$$

and therefore

$$T = \frac{1}{k(n-1)}\left(\frac{1}{q^{n-1}} - \frac{1}{p^{n-1}}\right)(\cos\bar{\gamma}')^{n-1}\left\{1 - \frac{n-1}{24}(\alpha-\beta)^2\left[\overline{n-2}(\sec\gamma)^2 - \overline{n-3}\right]\right\}$$

$$= \frac{1}{k(n-1)}\left(\frac{1}{q^{n-1}} - \frac{1}{p^{n-1}}\right)(\cos\bar{\gamma}')^{n-1}Q,$$

where Q has the same value as before.

Hence the values of X, Y, and T are as stated in my postscript to Mr. Niven's paper.

Although the method of finding the expressions for X and T given above, is perhaps the plainest and most straightforward that can be taken, the following leads to simpler operations.

Let $f(\phi) = u^l(\sec\phi)^{n+1}$.

Then $\int f(\phi)d\phi = \int u^l(\sec\phi)^{n+1}d\phi = \frac{g}{k}\int u^{l-n-1}\frac{du}{d\phi}d\phi$ by equation (1)

$$= \frac{g}{k(l-n)}u^{l-n} + \text{const.}$$

Hence

$$\int_\beta^\alpha f(\phi)d\phi = \frac{g}{k(l-n)}(p^{l-n} - q^{l-n})$$

Now let

$$F(\phi) = f(\phi)(\sec\phi)^m = u^l(\sec\phi)^{m+n+1},$$

then

$$F'(\phi) = f'(\phi)(\sec\phi)^m + mf(\phi)(\sec\phi)^m\tan\phi,$$

and

$$F''(\phi) = f''(\phi)(\sec\phi)^m + 2mf'(\phi)(\sec\phi)^m\tan\phi + mf(\phi)[m(\sec\phi)^m(\tan\phi)^2 + (\sec\phi)^{m+2}]$$

$$= f''(\phi)(\sec\phi)^m + 2mf'(\phi)(\sec\phi)^m\tan\phi + mf(\phi)[\overline{m+1}(\sec\phi)^{m+2} - m(\sec\phi)^m].$$

Hence, by the lemma,

$$\int_\beta^\alpha F(\phi)d\phi = (\alpha-\beta)\{F(\gamma) + \tfrac{1}{24}(\alpha-\beta)^2F''(\gamma)\}$$

$$= (\alpha-\beta)\left\{f(\gamma)(\sec\gamma)^m + \tfrac{1}{24}(\alpha-\beta)^2(\sec\gamma)^m[f''(\gamma) + 2mf'(\gamma)\tan\gamma + mf(\gamma)[\overline{m+1}(\sec\gamma)^2 - m]]\right\}$$

$$= (\alpha-\beta)(\sec\gamma)^m\left\{f(\gamma) + \tfrac{1}{24}(\alpha-\beta)^2[f''(\gamma) + 2mf'(\gamma)\tan\gamma + mf(\gamma)[\overline{m+1}(\sec\gamma)^2 - m]]\right\}.$$

But from above

$$\frac{g}{k(l-n)}(p^{l-n} - q^{l-n}) = \int_\beta^\alpha f(\phi)d\phi,$$

$$= (\alpha-\beta)\{f(\gamma) + \tfrac{1}{24}(\alpha-\beta)^2f''(\gamma)\}.$$

Hence, by division,

$$\int^\alpha F(\phi)d\phi \div \frac{g}{k(l-n)}(p^{l-n} - q^{l-n}) = (\sec\gamma)^m\left\{1 + \tfrac{1}{24}(\alpha-\beta)^2\left[2m\frac{f'\gamma}{f\gamma}\tan\gamma + m(\overline{m+1}(\sec\gamma)^2 - m)\right]\right\}$$

It will be noticed that in this division the quantity $f''(\gamma)$ has disappeared.

Now, from above,

$$f(\phi) = u^l(\sec\phi)^{n+1},$$

and therefore

$$\frac{f'(\phi)}{f(\phi)} = l\frac{du}{ud\phi} + (n+1)\tan\phi,$$

and

$$\frac{f'(\gamma)}{f(\gamma)} = l\left(\frac{du}{ud\phi}\right)_0 + (n+1)\tan\gamma.$$

Hence

$$\int_\beta^\alpha \mathrm{F}(\phi)d\phi \div \frac{g}{k(l-n)}(p^{l-n} - q^{l-n}) = (\sec\gamma)^m\left\{1 + \tfrac{1}{24}(\alpha-\beta)^2\left[2lm\left(\frac{du}{ud\phi}\right)_0\tan\gamma + 2m\overline{n+1}(\tan\gamma)^2 + m\left(\overline{m+1}(\sec\gamma)^2 - m\right)\right]\right\}$$

$$= (\sec\gamma)^m\left\{1 + \tfrac{1}{24}(\alpha-\beta)^2\left[2lm\left(\frac{du}{ud\phi}\right)_0\tan\gamma + m(m+2n+3)(\sec\gamma)^2 - m(m+2n+2)\right]\right\}$$

Now make $m + n + 1 = 2$,

or $m = -(n-1)$, and we have

$$\int_\beta^\alpha u^l(\sec\phi)^2 \div \frac{g}{k(l-n)}(p^{l-n} - q^{l-n}) = (\cos\gamma)^{n-1}\left\{1 - \tfrac{1}{24}(\alpha-\beta)^2\left[2l(n-1)\left(\frac{du}{ud\phi}\right)_0\tan\gamma + (n-1)(n+4)(\sec\gamma)^2 - (n-1)(n+3)\right]\right\}.$$

In this make $l = 2$, and $l = 1$, successively, and we obtain the same expressions for X and T as before.

The case thus treated is not one of mere curiosity, but is practically important. From theoretical considerations, Newton concluded that the resistance of the air to the motion of projectiles is proportional to the square of the velocity, and very little progress has been made in the theory of the subject since his time. Experiments have shown that the relation between the velocity of a projectile and the resistance offered by the air to its motion is far from being so simple as that given by the theory. The most extensive and accurate series of such experiments which we have are those made by Mr. Bashforth by means of his chronograph, which measures with the greatest precision the times taken by the same projectile in passing over several successive arcs in the course of its flight. In a summary of his results for ogival-headed shot, struck with a radius of $1\frac{1}{2}$ diameters, given in NATURE (vol. xxxiii. pp. 605, 606), Mr. Bashforth concludes that the resistance may be approximately represented by supposing it to vary as one power of the velocity when that velocity lies between certain limits, as another power when the velocity lies between certain other limits, and so on.

Thus, if v denote the velocity expressed in feet per second,

d the diameter of the shot in inches,

and w its weight in pounds,

and if $\dfrac{d^2}{w} = c$,

then, when v lies between 430 f.s. and 850 f.s.,

the resistance is nearly $= 61{\cdot}3\, c\left(\dfrac{v}{1000}\right)^2$;

when v lies between 850 f.s. and 1040 f.s.,

the resistance is nearly $= 74{\cdot}4\, c\left(\dfrac{v}{1000}\right)^3$;

when v lies between 1040 f.s. and 1100 f.s.,

the resistance is nearly $= 79{\cdot}2\, c\left(\dfrac{v}{1000}\right)^6$;

when v lies between 1100 f.s. and 1300 f.s.,

the resistance is nearly $= 108{\cdot}8\, c\left(\dfrac{v}{1000}\right)^3$;

and lastly, when v lies between 1300 f.s. and 2700 f.s.,

the resistance is nearly $= 141{\cdot}5\, c\left(\dfrac{v}{1000}\right)^2$.

Hence the resistance varies nearly as the square of the velocity both when the velocity is less than 850 f.s., and when it is greater than 1300 f.s., but the coefficient increases from 61·3 in the former case, to 141·5 in the latter. Also, the resistance varies nearly as the cube of the velocity, both when v lies between 850 f.s. and 1040 f.s., and also when it lies between 1100 f.s. and 1300 f.s., but the coefficient increases from 74·4 in the former to 108·8 in the latter case. Again, for velocities which are nearly equal to that of sound in air, the proportionate increase of the resistance is much greater than that of the velocity.

Mr. Bashforth remarks that the points of transition from one law of resistance to another, as stated above, are somewhat arbitrary, but that, if they were changed a little in either direction, the practical error would not be large.

Of course, if we had at our disposal much more numerous and still more accurate observations, it would be possible to represent the experimental results with any degree of exactness that might be desired, by subdividing the observations into a larger number of groups, so that the limiting velocities in any one group should be closer together, and that the change of the index of the power of the velocity in passing from one group to the next should be less abrupt.

J. C. ADAMS.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, December 19, 1889.—Dr. W. J. Russell, F.R.S., in the chair.—The following papers were read:—Frangulin, by Prof. T. E. Thorpe, F.R.S., and Mr. H. H. Robinson. The authors prepared the glucoside frangulin from the bark of the alder buckthorn (*Rhamnus frangula*), and find its formula to be $C_{22}H_{22}O_9$. On hydrolysis it yields a yellow product, $C_{15}H_{10}O_5$, which agrees in its properties with emodin, and a sugar which has the power of reducing Fehling's solution, and is not identical with dextrose.—Arabinon, the saccharon of arabinose, by Mr. C. O'Sullivan, F.R.S. The substance having an optical activity "well above $[\alpha]_j = 140$," obtained by the author by the hydrolysis of arabic acid, and described under the name of α-arabinose (Chem. Soc. Trans., 1884, 55), yields arabinose on hydrolysis, and appears to bear to this carbohydrate a relation similar to that which saccharon (cane sugar) bears to dextrose: the author therefore terms it arabinon. It has the formula $C_{10}H_{18}O_9$, and on hydrolysis gives a yield of arabinose agreeing very closely with that required by the equation $C_{10}H_{18}O_9 + H_2O = 2C_5H_{10}O_5$. As yet it has not been obtained in a crystalline state; it has a specific rotatory power of $[\alpha]_D = 198°{\cdot}8$, and 100 parts have the same cupric reducing power as 58·8 parts of dextrose.—On the identity of cerebrose and galactose, by Mr. H. T. Brown, F.R.S., and Dr. G. H. Morris. The authors give the results of an examination of a specimen of cerebrose, prepared from phrenosin, which was placed in their hands early in 1888 by Dr. Thudichum, who first isolated and crystallized this substance. They show that its specific rotatory power, cupric reducing power, and molecular weight as determined by Raoult's method, are identical with those of galactose, thus confirming the recent work of Thierfelder, *Zeit. Physiol. Chem.*, 14, 209) who has proved the sugar produced by the action of acid on cerebrin to be identical with galactose. In the discussion which followed the reading of the paper, Dr. Thudichum said that phrenosin, $C_{41}H_{79}NO_8$, consisted of the sugar now shown to be identical with galactose, $C_6H_{12}O_6$, of neurostearic acid, $C_{18}H_{36}O_2$, an isomeride of stearic acid, fusing at 84°, and of sphingosine, an

alkaloid of the formula $C_{17}H_{35}NO_2$. Some human brains contained as much as 4 per cent. of phrenosin in addition to other glucosides. The crystallized sugar (galactose) from phrenosin was always accompanied by an almost equal weight of uncrystallizable sugar, of which the nature was not yet ascertained.—The action of chloroform and alcoholic potash on hydrazines, Part 3, by Dr. S. Ruhemann. The products formed by the action of chloroform and alcoholic potash on hydrazines are to be regarded as derivatives of tetrazine, $N\begin{matrix}\diagup CH.NH \diagdown \\ \diagdown NH.CH \diagup\end{matrix}N$; and in the present communication the author describes the di-paratolyl,-orthotolyl, and -pseudocumyl derivatives of this base (cf. Chem. Soc. Trans., 1889, 242).

Royal Microscopical Society, December 11, 1889.—The Rev. Dr. Dallinger, F.R.S., Vice-President, in the chair.—Mr. E. M. Nelson read a short paper descriptive of a new semi-apochromatic objective which he exhibited.—Mr. C. Rousselet exhibited a small tank for Rotifers which could be readily moved about in such a way as to render an examination of the contents very easy, so that any desired specimens could be easily picked out. The lens used was a Zeiss's No. 6 Steinheil, the focussing being done by rackwork.—Mr. Crisp called attention to a number of stereoscopic photomicrographs of embryos, by Prof. Fol. They afforded a conclusive answer to the question brought forward at their meeting as to whether stereoscopic photomicrographic slides had been produced before that time.—Mr. Crisp read some extracts from a paper by Mr. Gill, which he was sorry to say was only handed in at the conclusion of their last meeting, as otherwise it could have been read then, and would have added to the interest of the specimens exhibited at the *conversazione*, which seemed almost conclusively to prove that the "markings" on certain diatoms were apertures.—Mr. A. W. Bennett gave a *résumé* of his paper on the freshwater Algæ and Schizophyceæ of Hampshire and Devon. It was the result of collections made, during his summer holidays, in the New Forest and on Dartmoor, many of the species being not only interesting, but also new to science.—Mr. Crisp reminded the Fellows present that at the last meeting mention was made of a new objective with an aperture of 1·60, the price of which was said to be £400. Some doubt was expressed at the time as to whether the account was true, but since then they had received several communications about it. A letter from Prof. Abbe, describing the principles of its construction, was read. Letters were also read from Dr. van Heurck, describing the performance of the lens, and inclosing a series of remarkable photomicrographs of diatoms taken with it, with magnifying powers of 10,000 and 15,000 diameters.

PARIS.

Academy of Sciences, January 6.—M. Hermite in the chair.—State of the Academy on January 1. Full lists are given of the Members of the various Sections. Amongst the foreign Associates and Correspondents occur the following English and American names:—*Associates:* Sir Richard Owen, Sir George Biddell Airy, and Sir William Thomson. *Correspondents: Geometry*—James Joseph Sylvester and George Salmon; *Astronomy*—John Russell Hind, J. C. Adams, Arthur Cayley, Joseph Norman Lockyer, William Huggins, Simon Newcomb, Asaph Hall, Benjamin Apthorp Gould, and Samuel Langley; *Geography and Navigation*—Rear-Admiral George Henry Richards; *General Physics*—George Gabriel Stokes; *Chemistry*—Edward Frankland and Alexander William Williamson; *Mineralogy*—James Hall and Joseph Prestwich; *Botany*—Joseph Dalton Hooker and Maxwell Tylden Masters; *Rural Economy*—John Bennet Lawes and Joseph Henry Gilbert; *Anatomy and Zoology*—James Dwight Dana, Thomas Henry Huxley, and Alexander Agassiz; *Medicine and Surgery*—Sir James Paget.—M. Duchartre was elected Vice-President for the year 1890.—Analogy of diamantiferous matrix in South Africa to meteorites, by M. Daubrée. It is argued that the South African diamonds were not formed *in situ*, but were erupted from great depths together with the fragmentary materials in which they are embedded. The presence of the diamond in the normal state and as carbonado, as well as transformed from graphite in various types of meteorites, is now placed beyond reasonable doubt. Attention is here called to the analogous conditions of association under which this crystal occurs in South Africa and in meteorites. M. Daubrée incidentally infers that the diamond is not, as is generally supposed, of vegetable origin, but is of inorganic nature, as is also the graphite occurring in analogous beds.—On some new fluorescent materials, by M. Lecoq de Boisbaudran. The author describes some new fluorescent appearances which he has obtained by employing samaria and the earths $Z\alpha$ and $Z\beta$ as agents, and calcined silica and zircon as solid solvents. Mr. Crookes's failure to obtain any fluorescences from samaria with SiO_2 and ZrO_2, he considers was probably due to their having been calcined at too low a temperature.—Observations of Borrelly's comet made at the Observatory of Algiers, by MM. Trépied, Ramraud, and Renaux. The observations are for the period December 23–30, when the nebulosity was somewhat elongated, and about 2′ in extent.—Observations of Brooks's comet (July 6, 1889) made at the Observatory of Nice with the 0·38m. equatorial, by M. D. Eginitis.—On the elliptic functions, by M. Paul Appell. It is shown that the representation of the elliptic functions by the quotient of Θ functions may be justified *a priori* by considerations which seem capable of being extended to the functions of two variables with four groups of periods.—On the rational integrals of equations of the first order, by M. P. Painlevé. Given a differential equation of any order, it is shown that the polynomes may always be found which verify the equation by determining a higher limit of their degree.—On the absolute value of the magnetic elements on January 1, 1890, by M. Th. Moureaux. These values are deduced from the mean of the horary observations taken at the Parc Saint-Maur on December 31, 1889, and January 1, 1890, and at Perpignan from the twenty-four horary observations taken on January 1.—On the refracting powers of the simple salts in solution, by M. E. Doumer. Owing to Mr. B. Walter's recent note in *Wiedemann's Annalen* (1889, No. 9, p. 107), M. Doumer here publishes somewhat prematurely the researches on this subject, which he has carried on for over five years, and during which he has dealt with 90 salts. He concludes that all salts formed by the same acid have the same molecular refracting power when they are constructed on the same type; that the refracting powers of salts belonging to different types are approximately multiples of the same number; lastly, that the molecular refracting powers of all salts are functions of the number of valencies of the metallic element entering into their construction.—Papers were read by M. Georges Vogt, on the composition of the rocks employed in China for the manufacture of porcelain; by M. Charles Combes, on matezite and matezo-dambose; by M. E. Guinochet, on the carballylates; by M. A. Lacroix, on the mineral-bearing cipoline marbles and the wernerite rocks of Ariège; and by M. Thoulet, on the sub-lacustrine relief, geology, and temperature of Lake Longemer (Vosges).

BERLIN.

Physiological Society, December 13, 1889.—Prof. du Bois-Reymond, President, in the chair.—Prof. Moebius spoke on a "drumming" fish (*Balistes aculeatus*) from Mauritius. During a recent visit to this island he observed a bright blue-coloured fish in the shallow waters of the harbour; when caught and held in the hand this fish emitted from its interior a most striking noise, like that of a drum. A careful examination of the animal failed to reveal any obvious movements, with the exception of one part of the skin, lying just behind the gill-slit, which was in continuous vibration. Nothwithstanding prolonged endeavours he had not been able to secure a second living example of this fish, and had hence been able to carry out his investigations on the cause of the drumming noise only on dead specimens. The portion of the skin (membrana supra-axillaris) which vibrates stretches from the clavicle to the branchial arch: it is provided with four large bony plates, and lies over the swim-bladder, which in this fish for the most part projects out of the trunk-muscles. Behind the clavicle lies a curiously-shaped long bone, which is attached to the clavicle at one point in such a way as to form a lever with two arms. The long arm of this bony lever (os post-claviculare) is embedded in the ventral trunk-muscles, and is capable of easy movement to and fro. The short arm slides during this movement over the rough inner side of the clavicle, and gives rise to a crackling noise, and this noise is then intensified by the swim-bladder, which lies in close proximity to the short arm of the lever, and acts as a resonator. When the trunk-muscles contract the body cavity is diminished in size, the air in the swim-bladder is driven forward, and the bladder then communicates the vibrations of the bony lever to the membrana

supra-axillaris, and the latter communicates them to the air. The speaker was of opinion that the above was the explanation of the "drumming" of this fish; he was, at all events, unable to find any other organ in it which could account for the noise. This noise is not known to be emitted by other species of Balistes, although it is known to occur in other groups.—Prof. Fritsch spoke on the anatomy of *Torpedo marmorata*. In opposition to the revolutionary views of many recent investigators, who deny the nervous nature of the ganglion-cells, he laid great stress upon the extremely close relationship which exists between the ganglia and end-organs, and is so strikingly shown in Torpedo. A thick nerve-fibre runs from each ganglion-cell to the electrical-organ, divides into twelve to twenty-three fibrils before it reaches the organ, and each of these fibrils is connected up with some one special plate of the organ. Now, since each plate, which is of hexagonal shape, owing to the close juxtaposition of the columns, receives one nerve-fibre at each of its angles, it hence follows that the number of the plates must be, on the average, three times as great as the number of the ganglia. The fibres of one ganglion supply eighteen plates, the latter (being hexagonal) require six times eighteen fibres for their supply, and since on an average eighteen fibres run out from each ganglion, it requires six ganglia to supply eighteen plates with nerves. The speaker had counted the plates of an electrical-organ in Torpedo, and obtained a number corresponding closely with an older enumeration of Valentin's made on a Torpedo of the same size; the number of plates he found to be 179,625. He had further counted the ganglion-cells which supply the plates with nerves and found them to number 53,739; this corresponds closely with the enumeration of Boll, who counted 53,760. The counting of ganglion-cells is subject to much uncertainty, chiefly owing to the fact that in sections of the central nervous system many cells are cut through, and are thus liable to be counted twice: hence the speaker had enumerated, most readily by means of photographs, the axis-cylinders of the nerves which supply the electric-organ; he found them to number 58,318, corresponding to the same number of ganglion-cells. The last number is nearly one-third the number of plates in the electrical-organ, and corresponds closely to the number which should be found if the older view is the correct one, that the ganglion-cells are the centres for the nervous end-organs.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, JANUARY 16.

ROYAL SOCIETY, at 4.30.—On the Chief Line in the Spectrum of the Nebulæ: Prof. J. N. Lockyer, F.R.S.—Observations on the Excretion and Uses of Bile: A. W. Mayo Robson.—On the Theory of Free Stream Lines: J. H. Michell.

LINNEAN SOCIETY, at 8.—Life-History of a Remarkable Uredine on Jasminum grandiflora: A. Barclay.—Certain Protective Provisions in some Larval British Teleosteans: E. Prince.

THURSDAY, JANUARY 23, 1890.

THE FUTURE INDIAN CIVIL SERVICE EXAMINATIONS.

THE importance of obtaining a satisfactory position for future science candidates in these examinations is now very great. We have not only to consider the need there is that the men selected should represent every side of modern thought and culture, but also to bear in mind the influence of such examinations on the development of education at home. It is unfortunately notorious that candidates offering science in the examinations conducted by the Civil Service Commission stand, as a rule, at a great disadvantage. The marks allotted to science subjects have often been relatively small, and even when outside pressure has secured the allotment of a fair proportion of marks to science, the methods adopted in conducting the examinations have, as has been pointed out in our columns and elsewhere, frequently been such as to prevent good candidates from actually obtaining an equitable proportion of them.

Now as the Commissioners, year by year, deal with thousands, we might say with tens of thousands, of candidates of various types and ages; and as their influence is by no means confined to the actual candidates examined, it is plain that we have in this organization a body whose influence, for good or ill, on education in this country is enormous. Therefore we regard it as most urgent that those who are familiar with this question should press the facts of the present case not only on the attention of the Civil Service Commission, but also at the India Office and on the notice of the public. We are happy to know, indeed, that the subject is being energetically taken up by a number of distinguished graduates of Cambridge. But the forces on the other side are very strong, and past experience of the action of the Commission has made it plain that the representatives of science have a serious task before them.

In their Report for 1888, the Commissioners have been at some pains to convince the public that their examinations have had a minimum disturbing effect on the ordinary course of education. For example, they show that at several recent examinations for Class I. clerkships in the home services, all, or nearly all, the successful candidates have been men of University education. The Commissioners should carry their investigations somewhat deeper, and ascertain how far these selected candidates represent all classes of University graduates. We have done this so far as opportunity has permitted; and the results of our investigation in the case of the Class I. clerkships (which alone we have at present examined, as it only affects the present question) do not bear out the contention of the Commissioners, but go to show that the examinations concerned are very distinctly calculated either to disturb the course of education or to fail to select men representing all the chief types of University culture.

From our results, which are given below, it is easy to foresee what it is that is to be feared under the coming scheme. For in the competition for Class I. clerkships, the major limit of age, twenty-four, is not far removed from that about to be adopted for future Indian Civil servants of the highest class. And in them, as we learn will be the case in the future examinations for the Indian service, no limit is placed on the number of subjects that may be selected from those which are examined.

We have before us the results of a number of these competitions held during the last ten or eleven years, and they show, as might have been expected from the scheme of marks, that science men are practically excluded. We have ascertained as far as possible the degrees taken by the successful candidates, and out of thirty we find that twenty-two have taken their degrees in classics, seven in mathematics, and one in natural science; whilst the marks of forty others, whose degrees could not be ascertained, show a similar preponderance of classical men. Now, when it is remembered that many men take honours in science at Oxford, that the number who do so at Cambridge is approaching that of those who take classical honours, and that scholarships are now given for science in considerable numbers at both Universities, it is plain that a scheme which is likely to produce such results as those we have quoted ought on no account to be adopted for the Indian Civil Service. Such a one-sided system of selection is not fair to the various classes of candidates, and it is not fair to the dependency which they will be charged to administer. The plain fact is that in the competition for the home services, the marks assigned to classics, mathematics, and science respectively are scarcely fair to mathematics, and very distinctly unfair to science. These branches of learning have been placed upon a far more equal footing at our Universities, and science candidates may fairly claim more equal treatment from the Commissioners in competitions such as those which we are now considering. In the examinations for first-class appointments in the home services, there is the enormous difference of 375 marks against science, out of 1250 in the effective mark values of classics and science. On a recent occasion the difference between the highest and lowest on the list of successful candidates was no more than 158, and although this is indeed a very exceptional case, it shows how enormous the effect of such a difference may be when the candidates are at all evenly matched.

Such a boycotting of the men of scientific training is deplorable enough in the selecting of men for the home services, but in the case of the future administrators of our Indian dependency it would be far more unfortunate. There, if anywhere, men of every type should play their part in the national work. The Cambridge men of science are doing their best to avert the catastrophe that we fear. We hope they will be supported promptly, universally, and energetically by their scientific brethren, both great and small.

THE SHAN STATES.

A Thousand Miles on an Elephant in the Shan States. By Holt S. Hallett. (London and Edinburgh: William Blackwood and Sons, 1889.)

MR. HALLETT'S journeys in Burmah, Siam, and the Shan States, in search of the best path to connect Burmah with China and Siam, were performed partly by boat, and partly on the back of elephants.

The problem before him was a difficult one, owing to the geography of Central Indo-China being unknown at the time of his visit. He has filled up a great blank in the map of this interesting region, and has proved that a practicable route for the railway exists, chiefly through great and fertile plains, to the populous parts of the Chinese province of Yunnan, and thence through Southern into Central China. The project has been for some years before the public, and has received the unanimous support of the manufacturing and mercantile communities, who have constantly, through the Chambers of Commerce, pressed the matter upon the attention of the Government. The Siamese section of the line, and several important branches, are now being surveyed and estimated for the King of Siam by English engineers, and are likely soon to be taken in hand.

The handsome volume before us contains an excellent index map of Southern China and Indo-China, five route maps, and nearly a hundred original illustrations. The index map shows clearly the projected Anglo-Siamese system of lines, and its continuation into Central China, together with the proposed branch to Pakhoi, the Southern Chinese seaport. On the same map are shown the rival lines which the French propose to construct in order to draw the trade of Southern and Central China and of the Shan States to a French port in Tonquin. The route maps, which are beautifully executed from Mr. Hallett's survey, have the population, geology, and height above sea-level of the country noted on them, which greatly increases their value. Apart from its commercial and geographical aspect, the book will prove of great interest to the politician and the general reader. It gives the account of an able, intelligent, and careful inquirer on the spot, concerning the position of the frontier of the British and Siamese Shan States at the time we annexed Upper Burmah, and it indicates the districts claimed by our new subjects which were then forcibly occupied by the Siamese. It describes the mode of government and the condition of the people in Siam and its Shan States, countries which are now being brought into close political and commercial relations with us. It treats of the threatened absorption of Siamese territory by the French, and shows how vast is our present stake in the country. It points out how imperative it is that we should pay close attention to the proceedings of the French, and safeguard our interests, which include the only known practicable route for the railway connection of Burmah with the populous and fertile regions of Southern and Western China.

The author expresses himself fluently and concisely. His descriptions of scenery, people, and wayside incidents, are extremely good, and the story of the journey is lightly, brightly, and amusingly told. He was exceptionally fortunate in his companions, and had no trouble in gaining the good-will and assistance of everyone he met during his travels. Dr. Cushing and Dr. McGilvary, who joined the party as interpreters, were masters of the Shan language, and, being missionaries, took a great interest in the welfare of the people. They had made a careful study of their manners and customs, and, having previously traversed the Shan States in various directions, were well known to the chiefs, nobles, and officials of the country. Another missionary, Mr. Wilson, who had resided at Zimmé for several years, afforded Mr. Hallett great assistance in collecting statistics and particulars of the trade of the country, and information about the religions, superstitions, and folk-lore of the various races. In the preface, Mr. Hallett gives an interesting history of the races found in Indo-China, and during his travels he collected several of their vocabularies. The aborigines of Lower Indo-China appear to have been Negritos, probably akin to those of the Andaman Islands and the hills of the Malay Peninsula. Other dwarf races of Negrito origin were met with on the journey, belonging to the Ka tribes in the neighbourhood of Luang Prabang. These are probably of the same stock as the Trao in Cochin China and one of the native races in Formosa, and are, in all likelihood, akin to the Tiao, a race of pygmies with whom the Chinese became acquainted when they entered North-Eastern China more than 4000 years ago. The Bau Lawa tribes met by him in the Shan States, and found in the hills as far south as the latitude of Bangkok, as well as the Mon race in Lower Burmah and the Cham or people of Cambodia, migrated into their present habitat at an early period, and are Mongoloid tribes of a race with Malaysian affinities. This Mon race is represented in Western Bengal and Central India by the Kolarian tribes. They are probably descendants of the Ngu stock, including the Pang, Kuei, and Miao tribes, who, with the Shan, Yang or Karen, and King or Chin tribes, formed the chief part of the population of Central and Southern China during the struggle for empire—604–220 B.C.

Other interesting tribes, known as La-Hu and Kiang Tung La-Wa, were met with by Mr. Hallett; and these are said to belong to the same white race as ourselves. They had already settled about the southern bend of the Hoang-ho at the time when the Chinese tribes arrived on the borders of China after their long journey from the neighbourhood of Chaldæa. Part of these various races have been gradually amalgamated with the Chinese, who have doubtless received from them and other races much of their folk-lore and superstitions. It may therefore prove highly interesting to compare the habits, customs, folk-lore, and superstitions of these early inhabitants of China with those of the Chinese. Many of the customs and superstitions must have been widespread at an early date. Mr. Hallett notices the strong similarity between some of the customs and superstitions of the Finnish tribes and those of the Shans. The book is rich in legends connected with various events which are said to have happened in the country. Some of these relate to the time when the Lawa were conquered or driven into the hills by the Shans; others relate to events which have since happened in the country; and the remainder are adaptations from Buddhistic stories, or refer to the guardian spirits of the country, or to romantic incidents that have occurred. The guardian spirits universally worshipped by the Shans are, strange to say, the spirits of ancient Lawa kings and queens reigning in the country at the time when wars were carried on between the Lawa and the Shans. Some of these local Sivas are believed to have ogre propensities, and formerly human sacrifices were offered up to them. Even the year previous to Mr. Hallett's visit, the execution of several criminals was hurried on in order to appease the local

Lawa spirits, so that they might be induced to allow the water needed for the irrigation of the fields to flow down from the hills. Human sacrifices at the obsequies of their chiefs were offered by the Shans up to the middle of the sixteenth century, when the States became feudatory to Burmah. At the time the chiefs were buried, elephants, ponies, and slaves were interred with them. The continuance of this custom was strictly prohibited by the Burmese Emperor Bureng Naung. Besides the legends, many humorous stories and fables are current amongst the people, specimens of which are given in the book.

Buddhism, with the Shans, as with the Chinese, is merely a cloak covering the belief in ancient superstitions, ancestral worship, and spirit worship of the people. Even the images of Buddha in the temples are believed to be inhabited by the spirits of deceased monks, and when an abbot, celebrated for his learning and virtue, dies, it is the custom for those who have spent their monastic life under his instruction to prepare a shrine for him in some part of their house, or, if still in the monastery, in their dormitory, where flowers and food are placed for the acceptance of the spirit of their deceased teacher. If he is treated with neglect or disrespect, he may become a spirit of evil towards his former pupils. This custom probably arises from the monks being celibate, and therefore having no children to carry on the ancestral worship of the family. Another peculiar practice in relation to the images of Buddha is the transferring to him of some of the attributes of the Kwan-yin, the Chinese Goddess of Mercy, the offspring of the lotus flower, who terminates the torment of souls in purgatory by casting a lotus flower on them. In China, miniature offerings are laid before this goddess as a hint for her to convey the articles implied by their likenesses to the spirits of friends or relations. The offerings, frequently accompanied by a scroll stating who the articles are for, consist of miniatures—cut out of paper—of money, houses, furniture, carts, ponies, sedan-chairs, pipes, male and female slaves, and all that one on this earth might wish for in the way of comfort. In Siam and the Shan States, there being no temple of this goddess, Buddha, who is generally depicted as sitting on a lotus flower, is besought to do her work, and similar things are heaped on his altar, but cut out of wood, or formed of rags or any kinds of rubbish, as paper is not easily obtainable. The whole country outside the villages is, according to the Shans, infested with jungle demons, the spirits of human beings who have died when absent from their homes. These endeavour to cause the death of others by the same means as caused their own. Their victims have to join the company or clan of demons to which the successful demon belongs. Thus the clan increases in numbers, and is ever becoming more potent for mischief. The people believe in divination, charms, omens, exorcism, sorcery, mediums, witchcraft, and ghosts. Witch-hunting rages throughout the country, and villages are set apart in which those accused of witchcraft must reside. Mr. Hallett noticed that the elephant-drivers every evening placed pieces of lattice-work on tall sticks stuck in the ground on the paths leading to and from the camp; and on inquiry he learned they were to entangle any evil spirit that might wish to enter the camp and injure the party. The Shans consider such precautions fully sufficient to ward off their malignant foes. The spirits, in their opinion, have as little intelligence as the birds of the air, and any scare-crow device will keep them at a distance. The spirits of those who die from abortion, miscarriage, or childbirth are much dreaded by the widower. If the child dies with the mother, its spirit joins hers in its rambles, endeavouring to harm the living. The first object of their search is the husband and father, whose death they do all they can to accomplish. Sometimes the man endeavours to escape by becoming a monk in a monastery far from his home. This belief, like most of the superstitions in Indo-China, is also current in China.

With reference to the condition of the people in the Shan States, Mr. Hallett says:—

"Nowhere in the Shan States is misgovernment and oppression of the people so rampant as in Siam. Taxation in the Shan States is exceedingly light; and the people are not placed under grinding Government masters, but have the power to change their lords at their will; they are not compelled to serve for three months in the year without receiving either wages or food; amongst them gamblers, opium-smokers, and drunkards are looked down upon and despised, and libertinism is nearly unknown. The only loose women seen by me in the Shan States were a few Siamese, who had taken up their quarters at Zimmé, the head-quarters of the Siamese judge."

Referring to Siam, he gives a fearful description of the oppression ruling in the country, and he says:—

"If it were not for slavery, serfdom, vexatious taxation and for the vices of the people, the Siamese might be a happy race. Living as they do chiefly upon vegetables and fish; in a country where every article of food is cheap; where a labourer's wages are such as to enable him to subsist upon a fourth of his earnings; where a few mats and bamboos will supply him with materials for a house sufficient to keep out the rays of the tropical sun and the showers in the rainy season; where little clothing is needed, and that of a cheap and simple kind; where nine-tenths of the land in the country is vacant, without owners or inhabitants—surely such a people might be contented and happy. The land is so fertile and the climate is so humid, that every cereal and fruit of the tropics grows there to perfection. Yet among the common people it is seldom a man or woman can be found who is not the slave of the wealthy or the noble. The Government battens on the vices of the people by granting monopolies for gambling, opium, and spirits. Government places the people under unscrupulous and tyrannical Government masters—merciless, heartless, and exorbitant leeches—who, unless heavily bribed, force the peasantry to do their three months' *corvée* labour at times and seasons that necessarily break up all habits of industry, and ruin all plans to engage in successful business. Government imposes taxes upon everything grown for human requirements in the country: fishing-nets, stakes, boats, spears, and lines, are all taxed. The Government net is so small that even charcoal and bamboos are taxed to the extent of one in ten, and firewood one in five, in kind. Fancy the feelings of an old woman, after trudging for miles to market with a hundred sticks of firewood, when twenty of the sticks are seized by the tax-gatherer as his perquisite! There is a land-tax for each crop of annuals sown, and paddy and rice are both subject to tax; so that three taxes can thus be reaped from one cereal. The burdensome taxation is levied in the most vexatious manner that can be conceived; for the taxes are let out to unscrupulous Chinamen, who are thus able to squeeze, cheat, and rob the people mercilessly. It is no use appealing from the tax-gatherer to the officials.

Money wins its way, and justice is unknown in Siam. Everyone who has not a friend at Court is preyed upon by the governors and their rapacious underlings. Such being the present state of Siam, one is not surprised to learn that the majority of its inhabitants, besides being slaves and selling their children, are libertines, gamblers, opium smokers or eaters, and given to intoxicating beverages."

Mr. Alabaster, the confidential adviser of the King of Siam, told Mr. Hallett that nine-tenths of the non-Chinese inhabitants of Bangkok were slaves; that "squeezing" was so universal amongst the nobility, officials, and monopolists, that no man could become rich in the country unless he purchased an appointment, and thus became one of the rulers; and that justice in the courts was a farce—the heaviest purse, or the most powerful person, invariably winning the case; besides which, if a man was believed to be in possession of money, false charges were brought against him, directly or indirectly, by the officials, in order to wring the money out of him. Everyone that he questioned in Bangkok was of opinion that the state of the people could not be much worse than it was at the time of his visit. According to an inspector of police in Siamese employ, the magistrates in that city have the reputation of being the biggest liars in the country, and the police are said to be the greatest thieves, and so unsafe are the people from false charges and lawsuits, that they willingly become the slaves of the powerful in order to gain their protection.

The whole volume is replete with interesting information; we heartily commend it to the attention of our readers.

THE LESSER ANTILLES.

The Lesser Antilles. A Guide for Settlers in the British West Indies and Tourists' Companion. By Owen T. Bulkeley. (London: Sampson Low, Marston, Searle, and Rivington, Limited, 1889.)

SINCE Mr. Froude wrote on the West Indies, numerous books and pamphlets have been produced, either to show he was entirely wrong, or to supplement in some important particular the information he gave respecting these islands. The author of the little book before us took note of Mr. Froude's lament that all hand-books to the West Indies "were equally barren" of facts connected with the higher interest which the islands possess for Englishmen, and he seeks to supply the deficiency.

Although it is evident that Mr. Bulkeley has not an intimate knowledge of all the islands concerned, this is no great disparagement—especially when we recall their comparative isolation, and the general ignorance which exists even in the West Indies themselves in regard to the affairs of their neighbours.

The facts stated are generally trustworthy, and the hints given to visitors and intending settlers are likely to be useful. There are a moderately good map and some twenty illustrations, most of which, however, are already familiar to us. Although usually grouped together, the several islands in the Lesser Antilles differ much more from each other than is usually supposed. One end of the chain, at the Virgin Islands, touches 19° N. lat., while the other end at Trinidad is in 10° N. lat. Hence, the extreme points of the Lesser Antilles are about six hundred miles apart, and there is such a diversity of soil and climate that each island really requires separate treatment.

There is still much misconception in the mind of the British public as regards the healthiness of these islands, and also as regards their suitability for settlers with a small capital. If there were someone in this country whose business it was to give accurate information respecting the West Indies, they would probably be greatly benefited.

The revival of interest in these islands, and the large number of people who annually visit them, are facts which have naturally led to the production of a guide-book. Mr. Bulkeley has, however, aimed at producing something more than a guide-book. The greater part of the volume is devoted to a minute description of the physical features, and the circumstances of the several islands, and this is followed by information for intending settlers, with the view of inducing those who have capital to invest to make their homes in these islands. While we cannot endorse all Mr. Bulkeley's statements on this latter point, it is only right to say that none of them are positively misleading, and at all times they are discussed with a modesty, and an evident desire to arrive at a right conclusion, that disarms criticism.

Besides the sugar-cane and cocoa-nut palms, there are industries connected with fruits, fibres, spices, annatto, arrow-root, pepper, maize, medicinal plants, scent-producing plants, coca, ramie, tea, tobacco, and many others well suited to the soil and climate.

It is well known that in former days large fortunes were made by sugar planters in the West Indies. Now, however, even the best estates do little more than give a small return on the capital invested, while many cannot even do this. It would be unwise, therefore, for the West Indies to confine their attention exclusively, or, indeed, largely, to the sugar-cane. Already a change is taking place. Jamaica has pimento, coffee, tropical fruits, cinchona, dye-woods, annatto, cacao; Trinidad has cacao, cocoa-nuts; Grenada is almost exclusively cacao and spices: Montserrat is noted for its lime plantations and lime-juice; while Dominica exports concentrated lime-juice, cacao, cocoa-nuts, as well as oranges to the neighbouring islands. The tendency is for the cultivation of the West Indies to become more and more diversified, and it is well it should be so.

With such good markets for produce of all kinds in the United States and Europe, it is evident that West Indian planters could regain much of their former prosperity if only they adapted themselves to the new order of things. To assist them in the development of new industries, Government botanical gardens are in course of being established, under the auspices of Kew, in every island, and from these new plants and information respecting their cultivation are being widely distributed. In such a work enterprising governors, such as the late Sir Anthony Musgrave, and the present Governor of Trinidad, Sir William Robinson, and others, have taken an active part. It is not, however, as regards industrial subjects only that interest in the West Indies has revived of late. The publication of Grisebach's "Flora of the British West Indian Islands" in 1864 (one of the series of colonial

flora projected by the late Sir William Hooker) was for a long time the only effort made in the cause of botanical science in this part of the world. Since that time, both the fauna and flora have received systematic attention in this country and in the United States, and after a lapse of nearly two hundred years we are beginning to have a clear idea of the distribution of life in the Caribbean Archipelago.

A Joint Committee of the Government Grant Committee of the Royal Society and of the British Association, has been engaged for the last three years in investigating ascertained deficiencies in the fauna and flora. Almost every page of Mr. Bulkeley's work affords ample evidence of the aid he has received, directly or indirectly, from the botanical efforts of recent years. More, however, might have been said of the special plants which are characteristic of the several islands, and which contribute so large a share to the interest of daily life in them.

It is to be hoped the day is not far distant when this first unpretentious guide-book to the Lesser Antilles will be followed by others, not less interesting, but still more fully meeting the requirements of those who may visit them for pleasure, or go to them in the hope of pursuing some of the numerous industries opened to settlers in these beautiful islands. D. M.

A TEXT-BOOK OF HUMAN ANATOMY.

A Text-book of Human Anatomy, Systematic and Topographical. Including the Embryology, Histology, and Morphology of Man, with special reference to the requirements of Practical Surgery and Medicine. By Alex. Macalister, M.A., M.D., F.R.S., Professor of Anatomy in the University of Cambridge. (London: Charles Griffin and Co., 1889.)

WHEN it was announced some time ago that the Professor of Anatomy in the University of Cambridge was engaged in writing a systematic work on Human Anatomy, its publication was looked for with anticipation and interest. Prof. Macalister deservedly enjoys a high reputation as a man of remarkable culture in many branches of knowledge, and as an anatomist in the comprehensive meaning of the term. Curiosity was excited, therefore, as to the mode in which he would treat the subject: whether he would follow the old lines pursued by so many of those who have preceded him in the writing of text-books, or if he would strike out a new path for himself.
